11 **Abstract** Mapping the distribution of invasive  
12 species under current and future climate conditions  
13 is crucial to implement sustainable and effective  
14 conservation strategies. Several studies showed how  
15 invasive species may benefit from climate change  
16 fostering their invasion rate and, consequently, affect-  
17 ing the native species community. In the Canary  
18 Islands and on Tenerife in particular, previous  
19 research mostly focused on climate change impacts  
20 on the native communities, whereas less attention has

been paid on alien species distribution under climate  
change scenarios. In this study, we modelled the  
habitat distribution of *Pennisetum setaceum*, one of  
the most invasive alien species on Tenerife. In  
addition, we described the species' potential distribu-  
tion shift in the light of two climate change scenarios  
(RCP2.6, RCP8.5), highlighting the areas that should  
be prioritized during management and eradication  
programs. *P. setaceum*'s suitable areas are located in  
the coastal area, with higher habitat suitability near  
cities and below 800 m asl. In both future climate  
change scenarios, the geographic distribution of *P.*

### 43 Introduction

44 Climate change is having strong ecological impacts on  
 45 biodiversity from the polar regions to the tropics, and  
 46 predicting the response of biodiversity to future  
 47 climate change scenarios has become a primary field  
 48 of research (Pereira et al. 2010; Bellard et al. 2012;  
 49 Matías and Jump 2013; Dyderski et al. 2018). Global  
 50 warming, along with the reduction in precipitation  
 51 during the growing season, may strongly alter species  
 52 distribution (Kleinbauer et al. 2010; Stocker 2014).  
 53 Furthermore, the increase in CO<sub>2</sub> atmospheric con-  
 54 centration and Nitrogen deposition promotes the  
 55 presence of invasive species and enhances the risk of  
 56 biological invasions (Dukes and Mooney 1999). In  
 57 this context, special attention should be paid to island  
 58 systems: islands are, in fact, at the forefront against  
 59 global changes such as sea-level rise and biological  
 60 invasions (Bellard et al. 2014; Pyšek et al. 2017).  
 61 Islands are well known to host habitats rich in rare and  
 62 endemic species; hence, more than one third of  
 63 biodiversity hotspots in the world are entirely, or  
 64 largely, within islands (Bellard et al. 2014).

65 Biological invasions are dramatically threatening  
 66 island biodiversity and ecosystem integrity (Hulme  
 67 2009; Scalera et al. 2012) since invasive alien species  
 68 (hereafter IAS, see Pyšek et al. 2004 for comprehen-  
 69 sive definitions) may directly reduce local plant  
 70 species diversity (Tordoni et al. 2019). However, the  
 71 deleterious effect of plant invasion is not limited to  
 72 competition with native species, but it could affect the  
 73 whole ecosystem, especially enclosed and fragile ones  
 74 such as islands. Firstly, changes in carbon and nitrogen  
 75 soil dynamics, resulting from alien plants invasions  
 76 (Vilà and López-Darias 2006; Vilà et al. 2011; Qian

and Ricklefs 2006), impact soil biotic community and  
 potentially alter important processes, such as mutual-  
 ism. In nutrient-enriched soils, for example, mycor-  
 rhizal populations can become antagonistic to hosts  
 (Toby Kiers et al. 2010). The balance in macroinver-  
 tebrate communities can be disrupted (Gremmen et al.  
 1998), with potential effects on the whole ecosystems.  
 Secondly, invasive alien plant species could promote  
 alien insect presence (Morales and Aizen 2002), which  
 has the potential to affect entire habitats and ultimately  
 alter ecosystem functioning and services (Kenis et al.  
 2009). Finally, recent studies suggest that IAS may  
 benefit from climate change (e.g. Kleinbauer et al.  
 2010; Brundu and Richardson 2016; Dyderski et al.  
 2018), which foster their invasion rate and, conse-  
 quently, invasion-related risks.

Due to the high rate of endemism (Whittaker and  
 Fernández-Palacios 2007; Fernández-Palacios et al.  
 2016), the Canary archipelago represents an extremely  
 vulnerable area for alien species invasions (Cour-  
 champ et al. 2003; Millennium Ecosystem Assess-  
 ment 2005; Kueffer et al. 2010; Bacaro et al. 2015).  
 Particularly, the island of Tenerife hosts a total of 9325  
 species, 1468 of them being vascular plants with 279  
 local endemic plant species (Arechavaleta et al.  
 2010). This island has been affected by an intense  
 human activity that altered the natural ecosystems,  
 causing fragmentation and the introduction of invasive  
 species in protected areas (Delgado et al. 2004), such  
 as fountain grass (*Pennisetum setaceum* (Forssk.)  
 Chiov.).

*Pennisetum setaceum* is a perennial, wind-dis-  
 persed, apomictic, C4 bunch grass native to North  
 Africa and the Middle East (Williams et al. 1995;  
 Poulin et al. 2007). It was introduced in the Canary  
 Islands as an ornamental plant and its presence has  
 been reported since 1940s (Hansen et al. 1970; de Paz  
 et al. 1999). Currently, it is considered one of the most  
 invasive species on Tenerife (Arechavaleta et al.  
 2010; Francisco-Ortega et al. 2009) as well as in  
 other areas (e.g. California, Hawaii, South Africa;  
 Williams et al. 1995; Poulin et al. 2007; Rahlao et al.  
 2010), constantly expanding its range along roads,  
 from urbanized areas toward natural ones (Martín Es-  
 quivel et al. 1995; González-Rodríguez et al. 2010).  
 Elevated phenotypic plasticity, characterised by vari-  
 ation in functional trait value according to the  
 environment, and its resilience, makes *P. setaceum*  
 well adapted to different ecological conditions (Poulin

et al. 2007; González-Rodríguez et al. 2010). Moreover, it can establish symbiosis with different local mycorrhizal fungi (AMF) communities, further promoting a successful establishment and spread (Rodríguez-Caballero et al. 2018). It is an aggressive invader of arid and semiarid coastal habitats such as thermoxerophilous grasslands and shrublands. Here, it establishes almost monospecific stands and causes long-lasting ecological consequences (Cordell and Sandquist 2008; González-Rodríguez et al. 2010). The species is known to have negative impacts on resources acquisitions in the dry forest plant communities and it can interact with the soil bacterial community, shifting its structure and composition, which can result in severe alterations of the N cycle (Rodríguez-Caballero et al. 2017). Moreover, it is a fire promoting species that can cause dramatic environmental changes, since fire is one of the most important drivers of land use and atmospheric changes globally (D'Antonio and Vitousek 1992). Finally, it can promote the presence of the alien invasive leafhopper *Balclutha brevis* (Bella et al. 2012). It has been estimated that approximately 30% of all protected areas of the Canary Islands have been invaded by fountain grass (Martín Esquivel et al. 1995; González-Rodríguez et al. 2010). Considering the dramatic effects that an uncontrolled increase in its distribution could create on Tenerife, understanding *P. setaceum* future habitat distribution is particularly important both from a conservational and ecological perspective, and it is a time-sensitive task.

Correlative models such as habitat suitability models (HSMs) have extensively been used so far to estimate the geographic distribution of a species based on an index of environmental similarity (Kearney 2006; Peterson et al. 2011; Guisan et al. 2017) which, in turn, is estimated starting from its occurrences in relation to its environmental determinants (Thuiller 2007; Steiner et al. 2008; Jiménez-Valverde et al. 2011). HSMs became a central tool in invasion biology, providing both interesting insight on species' ecology and practical suggestions for eradication management. For invasive species, the correct projection in space and time of HSMs estimates depends on different assumptions, which are defined by the research questions. It is fundamental to consider niche conservatism among native and invasive range when the research objective is to project the suitability index estimated in the native range into the invasive one.

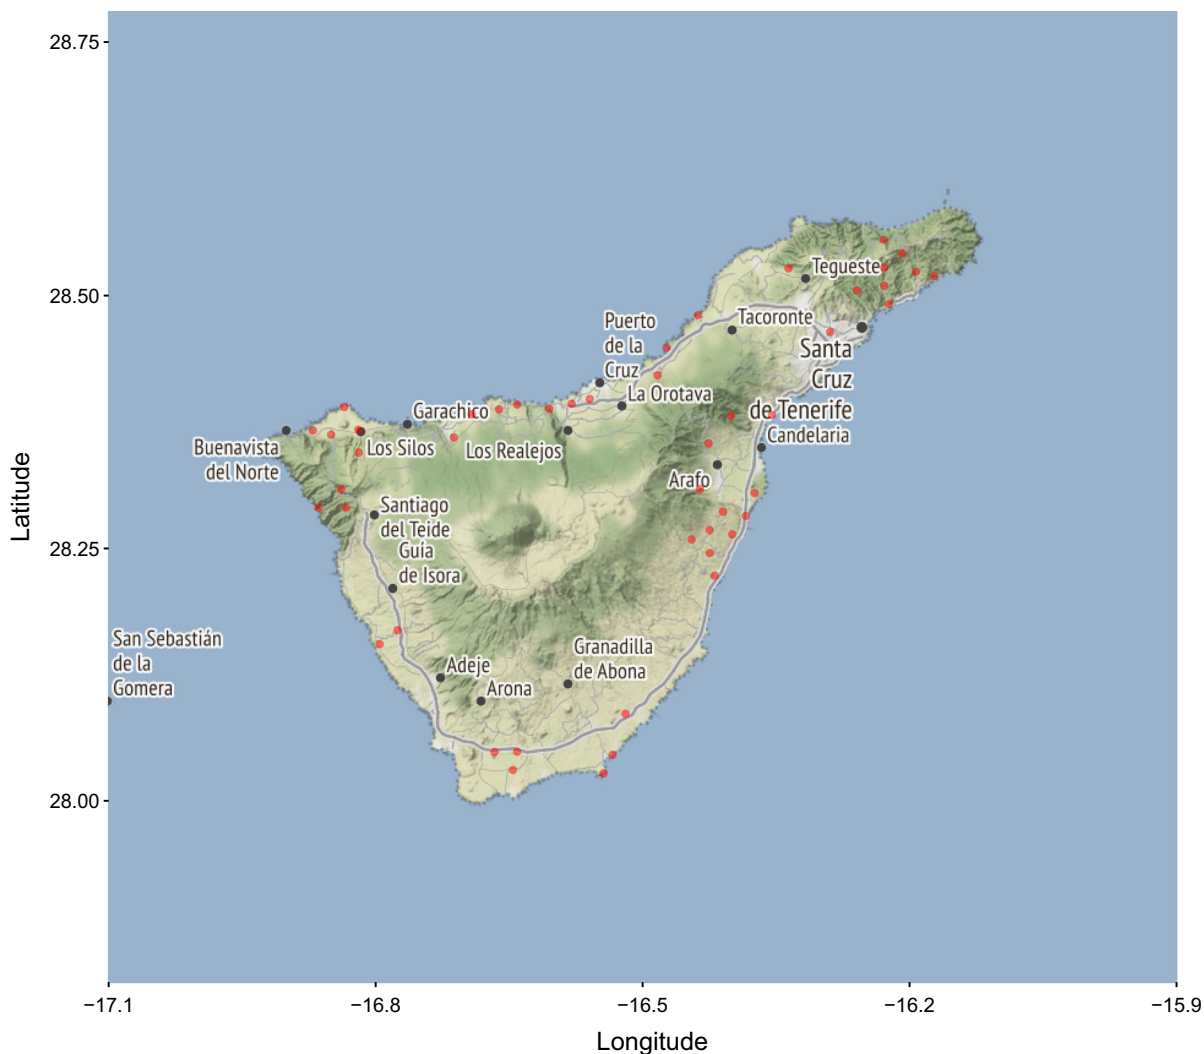

When using the species invaded range to train a HSM, the invasive species must be at quasi-equilibrium with the environment in which it occurs (Guisan and Thuiller 2005; Gallien et al. 2012). However, these assumptions are not always met, since the naturalized climatic niche of invasive species may differ from the natives climatic niches (e.g. Medley 2010; Early and Sax 2014) and since an invasive species is not at equilibrium with its environment until the latest stage of invasion (Barbet-Massin et al. 2018). Both cases result in a likely underestimate on the species predicted habitat suitability distribution. However, in situations where assumptions cannot be met for practical reasons (e.g. impossibility to compare native and invasive niche), HSMs may still provide predictions which are useful for invasive species management, such as highlighting the areas of likely expansion in the near future, which should be targeted and prioritized by conservation efforts (West et al. 2016).

Considering the importance of predictive tools to halt the loss of biodiversity, especially in relation to the spread of IAS fostered by climate change, here we aimed at (i) estimating *P. setaceum*'s current habitat distribution through HSM, across its' invaded range in Tenerife, and (ii) assessing the effect of climate change in shaping *P. setaceum*'s habitat distribution under two climate change scenarios (RCP2.6, RCP8.5). We hypothesize that *P. setaceum* may benefit from climate warming, increasing its current habitat distribution by spreading toward more humid zone of the island (e.g. at higher elevation), hence potentially increasing its impact on native habitats. Final goal of this study is to disclose a clearer image of those portions of Tenerife which will be more prone to the invasion process and therefore in urgent need of eradication and control activities.

## Materials and methods

### Study area

The study was carried out in Tenerife (27°–29°N, 13°–18°W; Fig. 1), the largest island of the Canary archipelago and the one with the highest elevation within Macaronesia (Mount Teide, 3718 m asl). Strong variations in elevation and aspect define local mesoclimatic zones and land uses that are primary

**Fig. 1** *Pennisetum setaceum* thinned occurrences distribution on Tenerife

220 factors in structuring both native and alien plant  
 221 communities on the Canary Islands (Whittaker and  
 222 Fernández-Palacios 2007). Mesoclimate is affected by  
 223 the trade winds that create a contrast between the  
 224 northern or windward aspect (more humid and  
 225 cloudier) and the southern or leeward aspect (more  
 226 arid and cloudless).

227 Response variable

228 Data of *P. setaceum* occurrences were obtained from  
 229 ATLANTIS (Gobierno de Canarias 2015), a regional  
 230 database containing IAS occurrences within a grid of  
 231 500 × 500 m square cells covering the entire

archipelago. Species records spanned in time from  
 1970 to 2017 but only those from 2005 to 2014 were  
 considered for the analysis in order to maintain data  
 consistency with the climatic data available. Only the  
 grid cells covering Tenerife landmass were selected  
 from the grid covering the whole Canary archipelago  
 (5515 selected out of 8519 total cells). This dataset  
 was complemented with records obtained by the Teno  
 Rural park internal database (Suppl. Mat.).

 241

242	Predictors		
243	Three abiotic variables were selected to predict		
244	species' habitat distribution based on previous knowl-		
245	edge on the ecology and biology of <i>P. setaceum</i> .		
246	Mean winter precipitation and mean spring precip-		
247	itation were chosen since the period October–March		
248	concentrates the 87.3 % of Canary Islands' annual		
249	precipitation (Sánchez-Benítez et al. 2017). More-		
250	over, it has been reported that in Mediterranean-type		
251	climate areas, <i>P. setaceum</i> germination occurs pri-		
252	marily in the Winter–Spring period (especially in		
253	December–January), followed by a constant decline		
254	towards the Summer due to moisture reduction		
255	(Hernandez and Sandquist 2011). Mean spring tem-		
256	perature was also selected, since it is known to be a		
257	limiting factor for alien species colonization along an		
258	elevational gradient, being usually correlated to ele-		
259	vation (Barni et al. 2012; Bacaro et al. 2015; Stein-		
260	bauer et al. 2017) and because the species has a		
261	maximum growth in warmer conditions (Sweet and		
262	Holt 2015).		
263	Finally, road kernel density was selected as a proxy		
264	of propagule pressure and species dispersion, espe-		
265	cially for <i>P. setaceum</i> (Foxcroft et al. 2019). Indeed		
266	anthropogenic activities enhance alien species' spread		
267	(Pyšek et al. 2010; Tordoni et al. 2017), and roads are		
268	known to be primary introduction pathways. Particu-		
269	larly, roadside may serve as invasion epicentres for		
270	annual species with high reproductive rates (Pauchard		
271	and Alaback 2004; Bacaro et al. 2015; Da Re et al.		
272	2019).		
273	Monthly precipitation of October–March periods		
274	and monthly temperature of March–May periods,		
275	spanning from 2005 to 2014, were obtained from		
276	Agencia Estatal de Meteorología (AEMET, accessed		
277	on April 2016). The methodology presented in Da Re		
278	et al. (2019) was used for filtering and the processing		
279	of the meteorological data in order to obtain contin-		
280	uous climatic interpolated surfaces through a co-		
281	Kriging procedure, using elevation as covariate (My-		
282	ers 1984; Garzón-Machado et al. 2014; Wilson and		
283	Silander 2014) and the R-package “geoR” (Ribeir-		
284	o et al. 2001). Road kernel density, calculated on the		
285	road network using 10 km regularly distributed sample		
286	points, was used here as a proxy of human disturbance		
287	and as a source of propagule pressure (Bacaro et al.		
288	2015; Da Re et al. 2019). The digital elevation model		
289	(DEM, 10 m of spatial resolution) and road network of		
	Tenerife Island were downloaded from Cartográfica	290	
	de Canarias S.A. (GRAFCAN, <a href="https://www.grafcan.es/">https://www.grafcan.</a>	291	
	<a href="https://www.grafcan.es/">es/</a> , accessed on March 2016), all the derived variables	292	
	were calculated using the grid spatial resolution as for	293	
	the IAS occurrences (500 m) (Table 1).	294	
	Climate change predictions	295	
	Temperature time series analysis of the Canary Islands	296	
	reported a temperature increase tendency, showing the	297	
	greatest increases on island summit (above 2000 m	298	
	asl) and above the cloud layer of windward mid-	299	
	altitude areas (Martín et al. 2012; Luque et al. 2014).	300	
	With regard to precipitation, there is no clear and	301	
	significant change (García-Herrera et al. 2003; Crop-	302	
	per and Hanna 2014).	303	
	Cropper (2013) estimates an increase in surface air	304	
	temperature of 1 °C and a decrease in water availabil-	305	
	ity of 15–20% due to more than 30% reduction in	306	
	precipitation (Giorgi 2006; Somot et al. 2008). In	307	
	order to get a reliable estimate of climate change	308	
	effects on the climatic variables considered (though	309	
	deemed approximate), we apply a constant correction	310	
	on interpolated climatic surfaces. Specifically, we	311	
	considered the two Representative Concentration	312	
	Pathways (RCPs), namely RCP2.6 and RCP8.5, as	313	
	described by the 5th Intergovernmental Panel on	314	
	Climate Change (IPCC) report representing possible	315	
	ranges of radiative forcing values in the year 2100	316	
	relative to pre-industrial values (+ 2.6 and + 8.5 W/	317	
	m <sup>2</sup> , respectively). Winter and Spring precipitations	318	
	were corrected by – 10.6% and – 36.7% (RCP2.6	319	
	and RCP8.5) according to Winter (December–Janu-	320	
	ary–February, DJF) precipitation reduction prevision	321	
	made by Cropper (2013), while for Spring, tempera-	322	
	ture values 0.96 °C (RCP2.6) and 2.68 °C (RCP8.5)	323	
	were added.	324	
	Habitat suitability modelling	325	
	HSMs were performed using Maxent v3.4.1 (Phillips	326	
	et al. 2017) through the R-package “dismo” (Hijmans	327	
	et al. 2017). Maxent estimates the relationship	328	
	between species occurrences and various environmen-	329	
	tal predictors, identifying areas with suitable environ-	330	
	mental conditions for the species, given a background	331	
	uniform probability of 0.5 (Elith et al. 2011). To	332	
	reduce the effects of sampling bias and thus avoiding a	333	
	possible source of model inaccuracy (Phillips et al.	334	

**Table 1** Predictors summary statistics at the occurrences locations

	Mean	SD	Median	Min	Max
October–March mean monthly precipitation	266.48	87.42	263.22	140.47	460.07
Mean spring temperature	18.00	1.00	18.24	15.54	19.93
Road kernel density	0.06	0.07	0.04	0.00	0.40
RCP2.6 October–March mean monthly precipitation	223.85	73.43	221.10	118.00	386.46
RCP2.6 mean spring temperature	18.96	1.00	19.20	16.50	20.89
RCP8.5 October–March mean monthly precipitation	168.68	55.33	166.62	88.92	291.22
RCP8.5 mean spring temperature	20.68	1.00	20.92	18.22	22.61

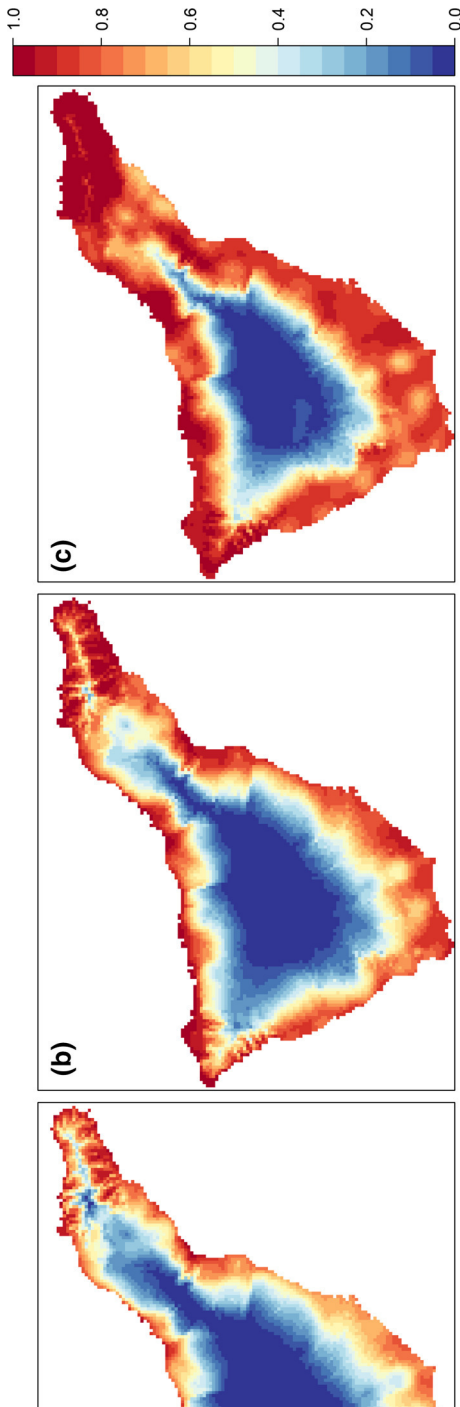

2006, 2009; Syfert et al. 2013), spatial filtering with a thinning distance of 2 km was applied to the *P. setaceum* occurrence dataset using the R-package “spThin” (Aiello-Lammens et al. 2015). The thinned occurrence data were then randomly divided into a training set and testing dataset applying a spatial block approach (Guevara et al. 2018; Roberts et al. 2017). Models with different combinations of feature classes (FC: Linear; Quadratic; Linear and Quadratic; Hinge; Linear, Quadratic, and Hinge) and beta regularization multipliers (RM: 0.5–5.0 with 0.5 intervals) were computed in order to avoid overfitting and to approximate optimal levels of complexity. The best model was then chosen based on Akaike Information Criterion corrected for small sample sizes (AICc, Warren and Seifert 2011; Muscarella et al. 2014). Following Guevara et al. (2018), we used all 8134-island pixel as background point to ensure a full representation of environments available for the species. The optimal settings obtained from above were used to train the final models using maxent.jar software. Model outputs were set as logistic response of the predicted distribution. The logistic output was then interpreted conservatively as a suitability index rather than as a probability (Merow et al. 2013) and it was evaluated using both the area under the curve (AUC) provided for the test data (Phillips et al. 2006), and the Boyce’s Index (Hirzel et al. 2006). The Boyce’s Index, computed through the “ecospat” R-package (Di Cola et al. 2017), ranges between  $-1$  (the model predict areas where presences are more frequent as being highly suitable for the species) and  $+1$  (the model predictions are consistent with the distribution of presences in the evaluation dataset), and values close to zero mean that the model is not different from random expectations (Hirzel et al. 2006). Finally, the

model was projected onto current, RCP2.6, and RCP8.5 climatic scenarios using unconstrained extrapolation (Guevara et al. 2018). The R codes used are available in the gitLab repository presented in the Supplementary Materials.

## Results

*Pennisetum setaceum* is mainly present in coastal areas, especially on the North-Western side of the island and near the largest cities (Santa Cruz de Tenerife, San Cristobal de La Laguna and Güímar on the N–E coast; Bajamar, Punta del Hidalgo, and Puerto de La Cruz on the N–W coast, Los Gigantes and Las Americas on the south; Fig. 2 and 2a).

48 occurrences (out of the original 227) were produced using the spatial thinning approach and then these were used to train the model. Model selection based on the AICc criteria pointed out that the most appropriate model was the one having linear, quadratic and product features and a beta regularization multiplier equal to 0.5 (Table 2). For this model, both Boyce’s Index and AUC suggested good performance in predicting species’ environmental suitability (AUC = 0.757; Boyce’s Index = 0.855, respectively). Temperature was the most important variable (88.6% of variable importance) followed by precipitation and roads density (8.7 and 2.7% of variable importance, respectively). Current suitable areas for *P. setaceum* mirrored occurrences’ distribution appearing prevalently below 800 m (Fig. 2). Model prediction based on the RCP2.6 scenario substantially confirmed as highly suitable areas, the current suitable ones, though a shift to higher values of habitat suitability can also be observed at higher elevation (Fig. 2b). An elevational

**Fig. 2** *Pennisetum setaceum* HSM predictions: **a** current climatic conditions, **b** RCP2.6 climatic conditions, **c** RCP8.5 climatic conditions

shift is emphasized by the model prediction based on the RCP8.5 scenario (Fig. 2c), where *P. setaceum* seems to climb up along elevation (especially in the northern part of the island on the Anaga mountains).

In warmer and drier climatic conditions, *P. setaceum* is likely to shift from lower to higher elevations, increasing the total area occupied by the species (Fig. 3). Indeed, estimates of habitat suitability indicate the preference of the species for climatic conditions with a mean spring temperature higher than 10 °C (Fig. 4).

**Discussion**

We investigated here the present and future spread of the invasive *P. setaceum* under different climatic scenarios, highlighting the current suitability of areas below 800 m asl (mirroring its current distribution; Supplementary Material Fig. 5), and predicting an increase in habitat suitability at higher elevations (~ 1000 m asl) for both future scenarios considered. Specifically, the predicted increase resulted particularly pronounced for the RCP8.5 scenario. Our predictions are quite alarming, considering that 800 m asl represents the current upper distribution limit of *P. setaceum* in Tenerife (Hobi 2008). *P. setaceum* is one of the most invasive species in Tenerife and it is currently spreading around the Mediterranean basin (Devesa Alcaraz et al. 2006; Pasta et al. 2010; Saavedra and Alcántara 2017). Our work is therefore particularly valuable to halt its spread via an effective monitoring of these areas that are under high invasion risk in the future.

Invaded habitats

*Pennisetum setaceum* spread below 800 m asl is likely to be enhanced by anthropic disturbance (e.g. land-cover change and consequent habitat fragmentation), rather than global warming. However, due to the year-by-year increase in anthropic disturbance and temperature at higher elevations, its present distribution is still expanding above 800 m asl (see for instance Kalwij et al. 2015). It has also been observed that *P. setaceum* can reach up to 2000 m asl in other islands contexts such as Hawaii (Williams et al. 1995). Moreover, *P. setaceum* has been recently observed at altitudes of 1500 m in the Barranco Risco Liso, located

within the Caldera de Taburiente in La Palma island (Walentowitz et al. 2019). Around Tenerife island, *P. setaceum* has rapidly colonized mainly areas that were already experiencing anthropic disturbance, such as agricultural and rural areas, spreading at higher altitudinal belts using the road network as the main propagation pathway like other IAS (Arteaga et al. 2009; Arévalo et al. 2010; Benedetti and Morelli 2017; Follak et al. 2018). In fact, in the area near Arafo, which has a long land-use history for agriculture, the species has climbed up approximately 100 m in elevation in three years (from 655 to 740 m asl, personal observation of DDR and ZNP in April 2019). *P. setaceum* established firstly along the roadside, and then it spread deeper into the surrounding landscapes, confirming that roads remain a crucial dispersion pathway for this species and could promote its spread into protected areas (Foxcroft et al. 2019; Walentowitz et al. 2019). However, its ability to compete and outstand native plant communities could be questioned in areas characterized by a high degree of biotic resistance and where the native community has sufficient propagule pressure for new colonization (Schuster et al. 2018).

*Pennisetum setaceum* also spread into many ravines within the lowlands in the South of Tenerife as well as into the lower parts of the National Park Caldera de Taburiente (Barranco de las Angustias), settling in semi natural communities (personal observations of RO). In ravines, called *barrancos* in Tenerife, temporary water flow during the rainy season facilitates the spread of seeds downriver, improving also the water supply in semiarid areas. However, in the southernmost part of Tenerife, *P. setaceum* probably is still limited by soil water conditions and at the highest sites of its distribution (currently at about 1000 m asl) low temperature might limit its growth. A still unanswered question is if *P. setaceum* will be able to grow and spread in open Canary pine forests growing above 800 to 1000 m asl, which might have serious consequences for natural regeneration and fire dynamics. However, according to Walentowitz et al. (2019), the dense canopy of forest ecosystems should prevent *P. setaceum* spread due to its heliophilous nature.

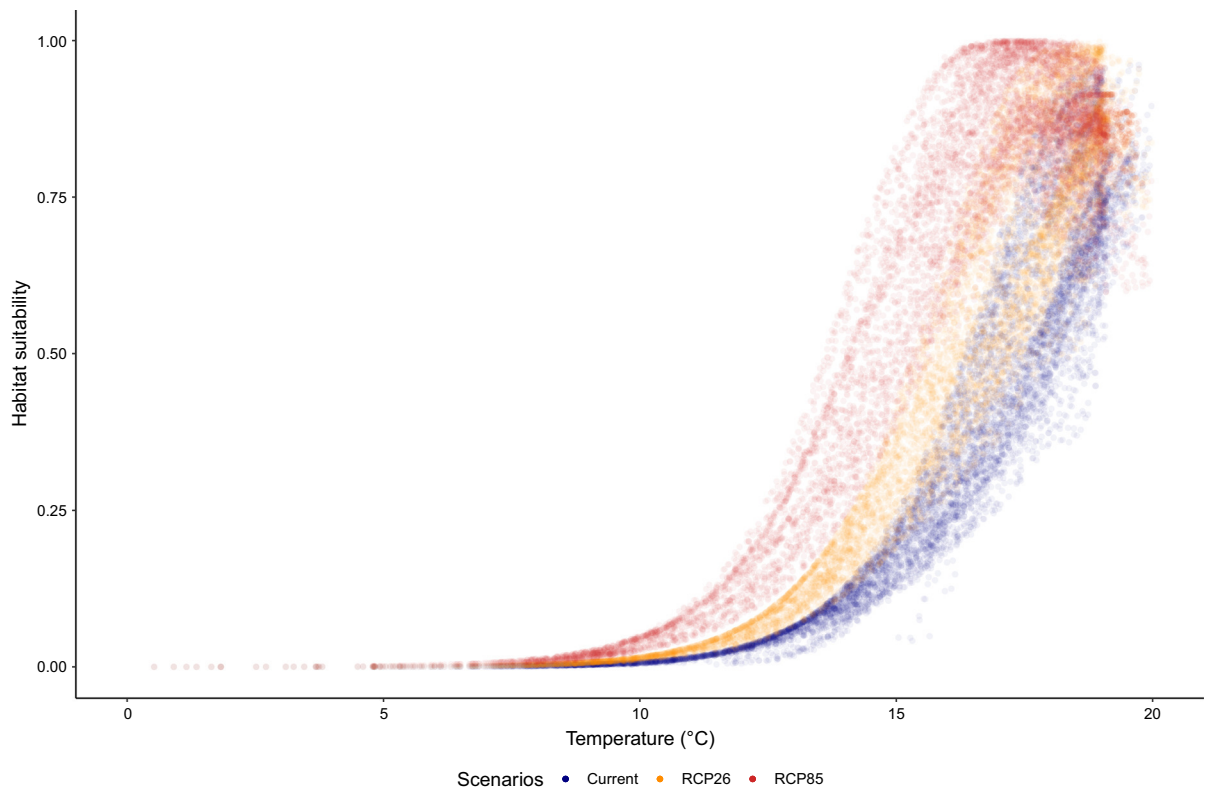

**Fig. 3** Relationships between *P. setaceum* HSM predictions and elevation: blue dots and line, current climatic conditions; orange dots and line, RCP2.6 climatic conditions; red dots and line, RCP8.5 climatic conditions

#### 492 Limiting factors, functional traits, and competitive 493 advantages

494 Generally, rainfall and temperature patterns are among  
495 the most important limiting factors determining plant  
496 distribution and abundance (Stephenson 1990), affect-  
497 ing reproduction and other life-history traits. Temper-  
498 ature is a strong limiting factor for the species, which  
499 usually prefers areas with temperature higher than  
500 10 °C (Fig. 4). Under the current conditions, these  
501 areas are located under 1000 m asl, but they are  
502 expected to rise under both the climate change  
503 scenarios analysed (RCP2.6 and RCP8.5). The geo-  
504 graphic distribution of the species in both scenarios  
505 showed an elevation shift, particularly pronounced in  
506 the RCP8.5 scenario. The species could move to  
507 higher elevation probably benefitting from the effect  
508 of orographic precipitations, and it could migrate in  
509 the north-western part of the island, where the trade  
510 winds enhance water availability (Figs. 2, 3). The  
511 ecophysiological traits of *P. setaceum* support its large  
512 size, extensive canopy, shorter leaf senescence period,

and the capacity to buffer seasonal and local water  
shortages (González-Rodríguez et al. 2010). Indeed,  
they confer considerable competitive advantages to  
the invader, and this can partially explain its invasion  
success in the Canary archipelago, considering local  
environmental and climatic conditions. On the other  
hand, seedlings' growth could be a limiting factor of *P.*  
*setaceum* invasion success: despite their relatively  
broad germination requirements, seedling cannot cope  
with low soil moisture or drought conditions (Adkins  
et al. 2011; Goergen and Daehler 2002), and it has  
been suggested that they do not tolerate more than one  
month of drought (Rahlao et al. 2010). Interestingly,  
once the seedlings are established, the amount of water  
does not seem to affect their performance, even under  
higher temperature regimes. When favourable condi-  
tions occur, *P. setaceum* can quickly thrive (already  
under sub-optimal ecological conditions) and over-  
come native coexisting species through rapid exploita-  
tion of available resources (such as water and  
nutrients), thanks to its broad ecological tolerance  
and high phenotypic plasticity (Williams and Black

**Fig. 4** Relationships between *P. setaceum* HSM predictions and temperatures: blue dots, current climatic conditions; orange dots, RCP2.6 climatic conditions; red dots, RCP8.5 climatic conditions

1993; Poulin et al. 2007; Rahlao et al. 2010). Furthermore, under drought or limited resources availability, the alteration of biomass allocation patterns in favour of roots seems to be a conservative strategy (Williams et al. 1995; Rahlao et al. 2010). This may explain why *P. setaceum* is an excellent invader of habitats characterized by fluctuating resources, frequently disturbed or with an irregular rainfall pattern, in agreement with Davis' theory of community invasibility (Davis et al. 2000). Compared to native species, the higher nitrogen and water use efficiency (González-Rodríguez et al. 2010) allow *P. setaceum* to compete effectively in warmer, drier areas, conferring it a considerable competitive advantage (Tordoni et al. 2020). Recently, Rodríguez-Caballero et al. (2017, 2018) have shown how *P. setaceum* could establish symbiosis with different mycorrhizal fungi and act as a transformer (Pyšek et al. 2004) modifying the soil bacterial community related to N cycle. As a consequence, it also tends to increase the risk of intense wildfires (to which it is well adapted), thus

posing a further threat to resident native communities (Tunison 1992).

Other studies on *P. setaceum* ecophysiology have confirmed the broad ecological tolerance of the species in other environments. Specifically, Jacobi and Warshauer (1992) reported that in the Hawaiian Islands, *P. setaceum* has a relatively wide elevation range (500–2900 m) but is limited to areas with median annual rainfall less than 1250 mm, hence only dry and mesic habitats are colonized by this species. In southern California, Sweet and Holt (2015) reported that *P. setaceum* might benefit from dampened temperatures and additional moisture through fog drip, becoming competitive in the cooler season due to phenotypic plasticity in response to temperature and water. Finally, since *P. setaceum* is endowed of C4 metabolism, it is likely that climate change may have positive effects on its performance, further promoting its invasion success, as already observed for other C4 invaders (e.g. Chuine et al. 2012 for *Setaria parviflora*). Indeed, C4 plants are intrinsically adapted to

577 elevated temperatures and to tolerate heat stress (Sage  
578 and Kubien 2003) thanks to higher effective quantum  
579 yield of CO<sub>2</sub> fixation, which increases photosynthetic  
580 rates, especially at higher temperatures (Ehleringer  
581 and Björkman 1977; Sage and Kubien 2003).

582 For the sake of clarity, we would like to highlight  
583 that a possible drawback of our predictions is the  
584 violation of the equilibrium assumption. In fact, it was  
585 not possible to consider the whole climatic range of the  
586 species and train the model including also occurrences  
587 present in native range: only 52 *P. setaceum* occur-  
588 rences are available in an area covering mostly the  
589 East Africa and the Arabian peninsula (Sudan,  
590 Ethiopia, Eritrea, Kenya, Somalia, Saudi Arabia,  
591 Yemen and Oman, GBIF accessed on 26th May  
592 2020). Considering, however, the invasion pressure  
593 that the delicate ecosystem of Tenerife is undergoing,  
594 predicting the areas that are more prone to invasion in  
595 the near future is more valuable (from a conservation  
596 and management perspective and under the precau-  
597 tionary principle; West et al. 2016) than modelling the  
598 full potential invasive range of *P. setaceum* at  
599 equilibrium. Nonetheless, considering the possible  
600 violation of this assumption, care must be taken when  
601 interpreting the model outputs.

## 602 Conclusions

603 Our model predictions highlight that the distribution  
604 of *P. setaceum* in Tenerife will be strongly affected by  
605 climate change and particularly by the predicted  
606 increase in aridity on the island. Our model (partic-  
607 ularly RCP8.5) foresees that the species would move  
608 to higher elevation and to the north-western part of the  
609 island, likely to benefit both from orographic precip-  
610 itations and enhanced water availability promoted by  
611 trade winds. Moreover, under the current socio-  
612 economic perspectives, the RCP2.6 scenario is becom-  
613 ing year after year less feasible (Davis and Socolow  
614 2014), making the RCP8.5 one even more likely. The  
615 species may consequently have negative impacts on  
616 entire ecosystems, due to its strong competitive  
617 capacities and being a driver of other invasive species.  
618 Particularly, the predicted invasion of areas at higher  
619 elevation poses the question of its ability to penetrate  
620 the pine forests (especially the more xeric ones in the  
621 southern part of the island). Its establishment could  
622 drastically affect the dynamics of this unique

ecosystem (e.g. natural regeneration, fire regime), if  
proper conservation plans will not be developed to  
support ecosystem health and diversity. However,  
even though our predictions are coherent with the  
auto-ecology of the species, climate change predic-  
tions are extremely simplified and should be therefore  
interpreted with care. More powerful outcomes may  
be obtained downscaling climatic data from global  
models such as Global Circulation Model (GCM), but  
to our knowledge spatially interpolated fine scale  
GCM projections for the Canary Islands are still  
lacking. Moreover, it has been showed that whereas  
global scale products are generally applicable at broad  
geographical scale, modelling climate surface on  
islands needs to consider fine scale spatial variation  
due to spatial variability and steep climatic gradient  
variation (Garzón-Machado et al. 2014; Khalyani  
et al. 2016). In a global warming scenario, a modelling  
approach as the one proposed here could play a key  
role in alien species monitoring, highlighting the  
portions of the territory that are more prone to  
biological invasions.

To our knowledge, Walentowitz et al. (2019) and  
ours results are the first *P. setaceum* niche model  
outputs presented. Such cartographic products provide  
an immediate tool for understanding potential changes  
in species distributions, and they can be used to  
disseminate and increase the awareness of biological  
invasion outside the academia. Considering the dra-  
matic effects that an uncontrolled increase of *P.*  
*setaceum* may have on Tenerife, understanding its  
future potential habitat distribution is therefore crucial  
from a conservational perspective. Immediate control  
measures (e.g. manual and chemical species removal  
efforts) should be carried out from the border of *P.*  
*setaceum* current distribution, focusing especially  
along invasion pathways (Walentowitz et al. 2019).  
Furthermore, prohibiting the commercial use of *P.*  
*setaceum* propagules could be another tool to control  
the species further spread. In fact, Potgieter et al.  
(2019) showed that ornamental plants are still per-  
ceived as having aesthetic benefits when confined to  
private gardens; however, shifts in perceptions may  
occur when they become widespread in the wild,  
leading to economic and environmental costs. Finally,  
specific Citizen Science projects have been shown to  
be effective to raise the awareness about biological  
invasions and to engage both public administrations  
and citizens in monitoring and controlling invasive
