ABSTRACT

We use a sample of 809 photometrically classified Type Ia supernovae (SNe Ia) discovered by the Dark Energy Survey (DES) along with 40 415 field galaxies to calculate the rate of SNe Ia per galaxy in the redshift range $0.2 < z < 0.6$. We recover the known correlation between SN Ia rate and galaxy stellar mass across a broad range of scales $8.5 \leq \log(M_*/M_\odot) \leq 11.25$. We find that the SN Ia rate increases with stellar mass as a power law with index 0.63 ± 0.02 , which is consistent with the previous work. We use an empirical model of stellar mass assembly to estimate the average star formation histories (SFHs) of galaxies across the stellar mass range of our measurement. Combining the modelled SFHs with the SN Ia rates to estimate constraints on the SN Ia delay time distribution (DTD), we find that the data are fit well by a power-law DTD with slope index $\beta = -1.13 \pm 0.05$ and normalization $A = 2.11 \pm 0.05 \times 10^{-13} \text{ SNe } M_\odot^{-1} \text{ yr}^{-1}$, which corresponds to an overall SN Ia production efficiency $N_{\text{Ia}}/M_* = 0.9^{+4.0}_{-0.7} \times 10^{-3} \text{ SNe } M_\odot^{-1}$. Upon splitting the SN sample by properties of the light curves, we find a strong dependence on DTD slope with the SN decline rate, with slower-declining SNe exhibiting a steeper DTD slope. We interpret this as a result of a relationship between intrinsic luminosity and progenitor age, and explore the implications of the result in the context of SN Ia progenitors.

Key words: supernovae: general – white dwarfs – galaxies: evolution.

1 INTRODUCTION

Type Ia supernovae (SNe Ia) are explosions of white dwarf stars (WDs). Although SNe Ia show diversity in their observed properties, a large fraction of them (‘non-peculiar’ SNe Ia) display a small dispersion in their peak brightnesses which can be reduced further through empirical relations between brightness and light-curve

properties, such as decline rate (stretch) or optical colour (Rust 1974; Pskovskii 1977; Phillips 1993; Tripp 1998). These properties have led SNe Ia to be used extensively by cosmologists to measure relative distances in the Universe (Riess et al. 1998; Perlmutter et al. 1999).

Despite using these relations to correct SN Ia peak brightnesses to within a dispersion of ~ 0.1 mag in samples with over one thousand SNe (Scolnic et al. 2018), the exact nature of the progenitors of SNe Ia is yet to be confirmed. While it is likely that SNe Ia are caused by mass transfer on to a WD from, or violent merger with, a companion star, multiple possible scenarios exist for the nature of that companion star (see Maoz, Mannucci & Nelemans 2014; Ruiter

* E-mail: p.s.wiseman@soton.ac.uk

2020 for reviews). The leading models involve a main-sequence (MS) star in the single-degenerate (SD) scenario (Whelan & Iben 1973; Nomoto 1982), a secondary white dwarf in the double-degenerate (DD) scenario (Tutukov & Iungelson 1976; Iben & Tutukov 1984; Webbink 1984), or more exotic models such as the core-degenerate (CD) scenario which invoke WDs merging with the cores of massive stars (Ilkov & Soker 2011; Kashi & Soker 2011)

The progenitors of several core-collapse SNe (CCSNe) have been identified in high-resolution pre-explosion images (Smartt 2009; Eldridge et al. 2013), allowing detailed analysis of the latter stages of massive star evolution. However, this approach has not yet been successful in identifying a progenitor of a SN Ia (e.g. Graur, Maoz & Shara 2014a; Kelly et al. 2014; Graur & Woods 2019, although see McCully et al. (2014) for evidence of a progenitor for a Type Iax SN). Conversely, there have been searches for surviving remnants of the binary system – main sequence stars or WDs left behind at the SN location or kicked out at high velocity (e.g. Schaefer & Pagnotta 2012; Ruiz-Lapuente et al. 2018; Kerzendorf et al. 2018, 2019). Promising recent results include that from Shen et al. (2018) who discovered three high-velocity WDs consistent with models of double-degenerate, double-detonation SNe Ia. However, without an unambiguous observation of an SN Ia progenitor system or remnant companion, there is as yet no direct evidence that any progenitor channel from provides a significant contribution to the total population of SNe Ia.

An indirect method of inferring progenitor channels is the study of the SN Ia delay time distribution (DTD). The DTD describes the rate at which SNe Ia occur as a function of the delay time τ since an episode of star formation, and thus carries characteristic signatures of the progenitor channel (see Wang & Han 2012 for a review of the theory, and Maoz & Graur 2017 for a review of observations). The SD scenario produces a broad range of functional forms for the DTD, most of which fail to account for long delay times (Graur et al. 2014b). On the other hand, most variants of the DD scenario predict a power law of the form τ^β , with $\beta \sim -1$ (e.g. Ruiter, Belczynski & Fryer 2009; Mennekens et al. 2010), although see e.g. Yungelson & Kuranov (2017) for DD models that deviate from a -1 power-law slope.

As a statistical distribution acting on time-scales from tens of Myr to several Gyr after an epoch of star formation, the DTD is non-trivial to measure and various techniques have been developed to infer it indirectly. One such approach is to measure global properties of SN Ia host galaxies. Simple examples of such analyses are comparisons of the rates of SNe Ia in hosts that have been split by some observational property, such as morphology or colour, and have shown that SN Ia rate per unit stellar mass (SNum) is significantly larger in late-type spiral galaxies as well as in bluer galaxies (e.g. Mannucci et al. 2005). These observations were interpreted as showing that SNe Ia are strongly influenced by recent or ongoing star formation, and thus that the majority of SNe Ia explode after short delay times. On the other hand, the SNum in E/S0 and red galaxies is also non-negligible, suggesting that there is a secondary, much older component to the DTD (Sullivan et al. 2006; Li et al. 2011; Smith et al. 2012). The DTD was thus approximated to first order by a two-component ($A + B$) model, where A and B are the normalizations of the DTD for ‘prompt’ (i.e. proportional to instantaneous SFR) and ‘tardy’ (i.e. proportional to overall stellar mass) SNe, respectively.

A complementary technique involves measuring the evolution of the volumetric rate of SNe Ia as a function of redshift and comparing this evolution to the average cosmic star formation history (CSFH) of the Universe (Dahlen et al. 2004; Gal-Yam & Maoz 2004; Strolger et al. 2004; Dahlen, Strolger & Riess 2008; Graur et al. 2011; Graur

& Maoz 2013; Rodney et al. 2014; Frohmaier et al. 2019). This technique (known as the volumetric rate method) is also applicable to galaxy clusters, for which it is assumed that the SFHs are strongly peaked at some past epoch and thus that the rate of SNe Ia in clusters as a function of redshift is a more direct measure of the DTD (Maoz & Gal-Yam 2004; Maoz, Sharon & Gal-Yam 2010; Friedmann & Maoz 2018; Freundlich & Maoz 2021). These studies have, almost ubiquitously, found β to be consistent with -1 .

Instead of comparing *volumetric* rates to the *cosmic* SFH, it is also possible to estimate the SFH of individual galaxies through the modelling of their stellar populations via spectral energy distribution (SED) fitting. Works such as Totani et al. (2008), Maoz et al. (2011), Maoz, Mannucci & Brandt (2012), Graur & Maoz (2013), and Graur, Bianco & Modjaz (2015) estimated the DTD by measuring SFHs for a sample of field galaxies and comparing them to the number of SNe detected in each galaxy (the SFHR method), and have led to results that suggest a DTD power law with β consistent with -1 .

Childress, Wolf & Zahid (2014, hereafter C14) showed that the $A + B$ approximation arises as a direct consequence of the combination of a power-law DTD with the average SFHs of galaxies – the prompt component proportional to the amount of ongoing star formation at the epoch of observation, and the tardy component caused by the fact that massive galaxies experienced high SFRs several Gyr ago. Recent advances in integral field spectroscopy (IFS) allow for an extension of the SFHR method, by reconstructing the SFH for hundreds or thousands of local regions of each SN Ia host galaxy. Using this method, Castrillo et al. (2020) find a power-law slope of -1.1 ± 0.3 , while Chen, Hu & Wang (2021) find -1.4 ± 0.3 .

The majority of observational evidence based on studies of SN Ia populations thus points towards a DD scenario for most, if not all, SNe Ia. However, finding self-consistent progenitor and explosion models that recreate the observed luminosity function as well as correlations between luminosity, light-curve parameters, and host galaxy properties has proven difficult. In particular, simulations based around explosions of M_{Ch} WDs (linked strongly with the SD scenario but also with many DD scenarios) find difficulty in reproducing the light curves of ‘normal’ SNe Ia as well as ‘peculiar’ objects (Ropke et al. 2007; Sim et al. 2013; see Maoz et al. 2014; Blondin et al. 2017; Jha, Maguire & Sullivan 2019 for overviews). In recent years, attention directed towards explosions of sub- M_{Ch} WDs triggered by double detonations (primarily related to a DD scenario) has led to promising results (e.g. Shen, Toonen & Graur 2017; Shen et al. 2018; Townsley et al. 2019; Gronow et al. 2020; Shen et al. 2021) although they still struggle to match observations at late times in the light-curve evolution (Gronow et al. 2021; Shen et al. 2021). An additional factor in support of the sub- M_{Ch} model is that the SN luminosity is related to the mass of the primary WD, which itself is likely to be related to its age (although this relation is probably complicated by other factors such as accretion rate, metallicity, and the composition of the companion), thereby providing an explanation for observed relation between light-curve stretch and stellar age (Rigault et al. 2013, 2020; Rose, Garnavich & Berg 2019; Nicolas et al. 2021). Other proposed scenarios include hybrid models in which standard CO WDs merge with hybrid helium-CO WDs (Zenati, Toonen & Perets 2019). With many models showing promising similarities to observations but each subject to its own drawbacks, it is becoming accepted that more than one progenitor scenario may contribute significantly to the overall population of ‘normal’ SNe Ia; detailed observations are thus required in order to place constraints on the relative fractions of each possible progenitor channel.

In this work, we combine parts of the traditional methods and derive a new measurement of the SN Ia DTD. Instead of measuring

the volumetric rate of SNe Ia, we measure the rate per galaxy as a function of stellar mass, as per Sullivan et al. (2006), Smith et al. (2012), and Brown et al. (2019). We use the stellar mass assembly model of C14 to predict the stellar age distribution of galaxies for a given stellar mass at the mean redshift of our SN sample, and then forward model the DTD by convolving it with the stellar age distribution and comparing the predicted rates to the observed rates.

In Section 2, we introduce our large sample of SNe Ia from the Dark Energy Survey (DES) as well as our deep sample of field galaxies that provide an effectively complete control sample from which to measure the rate. We describe our detailed handling of SN and galaxy incompleteness in Section 3. We present the SN Ia rate per galaxy in Section 4 and show that it is consistent with previous works. We outline our modelling of SFHs and our novel constraints on the DTD parameters in Section 5. In Section 6, we investigate how the DTD differs among subpopulations of SNe with different light-curve characteristics, in particular the stretch, and show stretch to be strongly dependent on progenitor age. We conclude in Section 7 by discussing the implications of the results. Where relevant, we assume a spatially flat Λ CDM cosmology with $\Omega_m = 0.3$ and $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$. Unless otherwise stated, we assume Gaussian measurement uncertainties quoted at the 1σ level, and we quote the posterior median and 1σ credible intervals on derived parameters. Magnitudes are quoted in the AB system (Oke & Gunn 1983).

2 DATA

In order to measure the rate of SNe Ia per galaxy per year, we require a sample of SNe Ia, as well as a sample of all of the possible galaxies (‘field’ galaxies) that those SNe could have exploded in. In practice, SN and galaxy surveys do not cover the same sky area, redshift ranges, times, and have different selection biases. In this section, we introduce our SN and field galaxy samples and in Section 3 we describe our method of correcting the selection effects for both the SN and field galaxy samples.

2.1 Dark Energy Survey supernova programme

To derive our sample of SNe and field galaxies, we make use of the DES. The DES Supernova Programme (DES-SN) was a transient survey based on five six-month seasons of observations of ten Southern hemisphere fields with the Dark Energy Camera (DECam; Flaugher et al. 2015). The SN survey was designed primarily to measure the light curves of SNe Ia for use as cosmological distance indicators. Transients were detected and processed using a difference imaging pipeline (Kessler et al. 2015) and image-subtraction artefacts were rejected using a machine learning (ML) algorithm (Goldstein et al. 2015). Spectral follow-up of live SN candidates was performed on a suite of large optical telescopes (Smith et al. 2020a), leading to the initial publication of a measurement of cosmological parameters using 207 spectroscopically confirmed SNe Ia (DES Collaboration 2018, and references therein). Spectroscopic redshifts for host galaxies come from the OzDES Global Redshift Catalog (GRC;¹ Yuan et al. 2015; Childress et al. 2017; Lidman et al. 2020), which comprises galaxies targeted as DES-SN hosts with the OzDES programme as well as redshifts from legacy catalogues in the DES-SN fields.

2.2 Supernovae

2.2.1 Photometric classification and quality cuts

With over 30 000 discovered transients it was not possible to obtain spectral follow-up of every object. Instead we make use of photometric classification in the form of the recurrent neural network classifier `superNNova` (SNN; Möller & de Boissière 2019), following the approach of Scolnic et al. (2020). A full description of the training and fitting of SNN will be presented in Vincenzi et al. (in preparation) and Möller et al. (in preparation); we provide a brief overview here.

We train SNN using a large suite of simulated multiband SN light curves and their associated host galaxy redshifts, using its default architecture. SNe Ia are simulated based on the SALT2 model (Guy et al. 2007) trained on the Joint Lightcurve Analysis (JLA) data set (Betoule et al. 2014) using an identical method to that described in detail in Vincenzi et al. (2020), and based on the workflow outlined in Kessler et al. (2019). We simulate SNe using the SuperNova ANALYSIS software (SNANA; Kessler et al. 2009) integrated into the `pippin` framework (Hinton & Brout 2020). SALT2 parameters x_1 (stretch) and c (colour) are drawn randomly from the intrinsic asymmetric Gaussian distributions described in Scolnic & Kessler (2016) and ‘blurred’ following the intrinsic scatter model of Guy et al. (2010), while redshifts are drawn following the volumetric rate evolution of Frohmaier et al. (2019). Synthetic CCSNe light curves are generated from the templates of Vincenzi et al. (2019), with a rate following the CSFH of Madau & Dickinson (2014) and normalized by the local Universe rate of Frohmaier et al. (2020).

Given the training set of synthetic light curves, SNN returns a classification (SN Ia, CCSN, or peculiar) for observed light curves. Before classifying, we remove transients with variability in multiple seasons (likely active galactic nuclei or superluminous SNe). SNN is then run on every transient with a host galaxy redshift (see Section 2.2.2). We define SNe with a threshold probability of $P(\text{Ia}) \geq 0.5$ as photometrically classified SNe Ia, although our analysis is not sensitive to this choice, since the vast majority of SNe receive classifications close to 1 or 0. The photometrically classified SNe Ia are then passed through a SALT2 light-curve fitting code and are subject to quality cuts on x_1 and c in an identical manner to Vincenzi et al. (2020): $-3 \leq x_1 \leq 3$, $-0.3 \leq c \leq 0.3$. This selection helps to reduce the potential contamination from core-collapse SNe (CCSNe) and outlying thermonuclear SNe, as well as removing those in extremely dusty environments. We impose further cuts on the quality of those measured parameters, which are: the uncertainty on x_1 : $\sigma_{x_1} < 1$; the uncertainty on the date at which the light curve has peak brightness: $\sigma_{\text{peak}} < 2 \text{ d}$; the SALT2 fit probability² > 0.01 . The number of SNe passing each stage of these cuts is displayed in table 2 of Vincenzi et al. (2020) and reduces the $\sim 30,000$ objects to 1604 SNe. With the addition of the photometric classifier we are left with 1441 SNe with which we proceed to inspect their host galaxies. While the inclusion of stringent cuts significantly reduces the size of the sample, it greatly enhances the purity and is in line with previous rates analyses of this nature (Sullivan et al. 2006) as well as being consistent with other DES-SN analyses (e.g. Kelsey et al. 2021). The contamination of this sample from CCSNe according to the simulations of Vincenzi et al. (2020) is expected to be below 3 per cent, which is close to that of spectroscopic samples (Rubin et al. 2015).

²Based on light-curve fit χ^2 and number of degrees of freedom.

2.2.2 Host galaxy selection

Host galaxies for all transients in DES-SN are retrieved from the DES-SN Deep catalogue, a galaxy catalogue from the g, r, i, z -band coadded images of the ten DES-SN fields which was presented in Wiseman et al. (2020). SNe are associated to galaxies using the directional light radius (DLR) method (e.g. Sullivan et al. 2006; Gupta et al. 2016). As is standard across DES-SN analyses, we require a SN-host separation to DLR ratio (d_{DLR}) less than 4 in order to classify a galaxy as a host. In the case where multiple galaxies lie within $d_{\text{DLR}} < 4$, the object with the lower or lowest value is taken to be the host.

2.3 Field galaxies

To calculate the SN Ia rate per galaxy as a function of stellar mass we require a representative sample of the global galaxy population, which we call our field galaxy sample. In order to maintain consistency between the SN host and field galaxy sample selections, we obtain a field galaxy sample from the same catalogue as that from which the SNe are matched to obtain host galaxies (SN Deep; Wiseman et al. 2020). The steps relevant to this analysis are outlined in the following sections.

2.3.1 Photometric redshifts

Since the vast majority of objects detected in the SN Deep catalogue do not have a spectroscopic redshift measurement, we rely on photometric redshifts (photo- z s). Photo- z s are taken, from the DES Y3A2_DEEP catalogue of Hartley et al. (2020). Y3A2_DEEP makes use of the same deep DES optical photometry that was used in SN Deep for a subset of the fields (SN-X3, SN-C3 and SN-E2), but adds DECam u -band data and near-infrared (NIR) J, H , and K -band imaging from the ultraVISTA and VIDEO surveys. The deep optical photometry in Y3A2_DEEP was stacked using a different technique to that of SN Deep, but the resulting photometry is consistent within 1σ uncertainties (Wiseman et al. 2020, Meledorf et al. in preparation). Hartley et al. (2020) estimated photo- z s using the `eaZy` code (Brammer, van Dokkum & Coppi 2008). Photo- z accuracy from Hartley et al. (2020) at $17 < i < 24$ is estimated around 0.03 as quantified by the Normalized Median Absolute Deviation (NMAD). This accuracy is degraded to 0.07 at $17 < i < 26$, a range that includes all galaxies in our sample, but is more than adequate for the purposes of this work, where all field galaxies will be grouped into stellar mass bins of $\log(\Delta M_*/M_\odot) = 0.25$. A detailed description of the photo- z accuracy and its dependence on redshift and apparent magnitude is presented in Hartley et al. (2020).

2.4 Quality cuts

In order to refine the sample of host and field galaxies for the rate analysis we perform a series of quality cuts:

- (i) objects must be detected and have a Kron magnitude measurement in all four DES optical bands;
- (ii) field galaxies are limited to unmasked region of the SN-X3 field (Hartley et al. 2020) which has an area of 1.52 deg^2 ;
- (iii) objects must not be within a given number (20 in x , 50 in y) of pixels of the CCD edge, as the co-addition of slightly misaligned images introduced a region of significant noise in this part of the detector;

Table 1. Numbers of field galaxies and SN hosts passing various quality cuts. SNe are derived from must already have passed the masked chips and good redshift cuts before reaching this stage.

| Cut | N (field galaxies) | N (SN hosts) |
|--------------------------------|----------------------|----------------|
| Chosen fields | 1 364 311 | 1441 |
| Kron mag in all bands | 1 069 004 | 1439 |
| Masked chips | 816 950 | - |
| Has <i>ugrizJHK</i> photometry | 545 748 | - |
| Edge of chip | 481 731 | 1401 |
| Star/galaxy separation | 400 051 | 1259 |
| Has good redshift | 395 034 | - |
| SNR ≥ 3 | 338 256 | 1259 |
| $m_r \leq 24.5$ | 196 109 | 1254 |
| $0.2 \leq z \leq 0.6$ | 48 177 | 809 |

(iv) to minimize stellar contamination, objects must have a value of < 0.95 in at least one band for the star/galaxy (S/G) separation metric `CLASS_STAR` provided by `Source Extractor` (Bertin & Arnouts 1996);

(v) field galaxies must be covered by *ugrizJHK* photometry, with a photometric flux measurement or upper limit present in all bands;

(vi) objects must have a spectroscopic redshift measurement or a photometric redshift estimate with a well-defined peak in redshift probability density;

(vii) objects must be detected at signal-to-noise ratio (SNR) greater than 3 in the r band;

(viii) galaxies must be brighter than $m_r \leq 24.5$, as this is the magnitude of the faintest SN host with a spectroscopic redshift;

(ix) galaxies must be within the redshift range $0.2 \leq z \leq 0.6$ (see Section 3.1 for an explanation of this cut).

The numbers of SN hosts and field galaxies passing these cuts are listed in Table 1. The final samples comprise 809 SNe and their host galaxies and 40 415 field galaxies. The volume-weighted mean redshifts are 0.50 for both SNe and field galaxies.

2.5 Galaxy properties

We estimate global galaxy properties for both the SN host and field galaxies that pass the quality cuts by fitting the photometry with stellar population templates in a method outlined by Sullivan et al. (2006) and consistent to that used in previous DES-SN analyses (Wiseman et al. 2020; Smith et al. 2020b; Kelsey et al. 2021). For SN hosts the redshift is fixed at the spectroscopically determined value, while for field galaxies we fix it at either the spectroscopic value if one exists in the OzDES GRC, or more commonly the photometrically derived value. We use the stellar population templates of Bruzual & Charlot (2003) and adopt a Chabrier (2003) initial mass function (IMF). The fitting procedure returns a best-fitting template and corresponding stellar mass (M_*). Upper and lower bounds on stellar mass estimates are taken as the extreme values that correspond to templates that are consistent with the data (given the photometric uncertainties) according to their χ^2 statistic, as per Sullivan et al. (2006). To check for bias caused by template choices, we also fit the galaxies using the PÉGASE.2 templates (Fioc & Rocca-Volmerange 1997; Le Borgne & Rocca-Volmerange 2002) and a Kroupa (2001) IMF, and find results consistent within measurement uncertainties. This is consistent with the findings of Smith et al. (2020b).

The results of our SED fitting are shown in Fig. 1. The figure showcases the vastly different distributions of the two samples. SN hosts are preferentially high-mass galaxies, whereas the field

Figure 1. Upper: Distribution of the stellar mass of the SN host galaxies. The raw (green dashed) and spectroscopic-efficiency-weighted (blue dot-dashed; Section 3.2) histograms are both normalized. Comparison samples are PTF (purple; Pan et al. 2014) and Pantheon (orange; Scolnic et al. 2018). Lower: As upper but for field galaxies, and with galaxy frequency shown on a log scale. The distribution closely matches data from the ZFOURGE survey at $0.5 < z < 0.75$ (magenta dots). The difference between the raw counts (grey dotted) and the V_{\max} corrected counts (orange solid; see Section 3) is minimal.

galaxy distribution increases down to lower masses, peaking around $10^{8.5} M_{\odot}$. The SN host stellar mass distribution is plotted twice: once as raw counts; once weighted by the host galaxy spectroscopic efficiency (Section 3.2). As shown in Fig. 1, the host stellar mass distribution of the DES-SN sample used in this analysis is qualitatively similar to that from the low redshift Palomar Transient Factory (PTF) sample (Pan et al. 2014) as well as the large cosmological Pantheon sample (Scolnic et al. 2018). This consistency reflects that seen in the smaller spectroscopically confirmed samples presented in Wiseman et al. (2020) and Smith et al. (2020b). The field galaxy stellar mass distribution is shown on a log scale, along with the stellar mass function (SMF) from the ZFOURGE survey (Tomczak et al. 2014) scaled to match at $\log(M/M_{\odot}) = 10$, whose stellar masses are derived with the same photo- z code, IMF and template library as used here. Above $10^{8.5} M_{\odot}$, the DES field galaxy distribution closely follows the ZFOURGE SMF for $0.5 < z < 0.75$, indicating that the DES sample is representative of field galaxies in this mass and redshift range.

3 INCOMPLETENESS CORRECTIONS

The simple ratio of the number of SN hosts and field galaxies presented at the end of the previous section provides a first approximation of the SN rate per galaxy, and the inclusion of a factor equal to the survey duration normalizes the rate to per year. However, both the SN and field galaxy samples introduced in Sections 2.2 and 2.3 are affected by incompleteness, which is likely to be the dominant systematic effect in the analysis. In this section, we describe our method of correcting for various sources of incompleteness in the data.

3.1 Supernovae

Incompleteness in a SN survey arises from a number of sources. The primary source of incompleteness is caused by the magnitude

Figure 2. SN detection efficiencies split by DES-SN field, x_1 and c . The y -axis represents the fraction of simulated SNe in a given redshift bin that would have been detected by DES-SN and passed light-curve quality cuts. Lines are polynomial fits that approximate the efficiency curves.

limit of the survey: SNe with apparent magnitudes below the survey limit will not be detected. Since SNe Ia are relatively uniform in absolute luminosity, this form of incompleteness is primarily redshift dependent. The large redshift range of DES-SN also means that SNe are probed at different regions of their rest-frame SED that vary significantly in luminosity. Additionally, DES-SN comprises 10 separate pointings, each with different visibility and thus airmass throughout the observing season. These differences lead to different detection efficiencies across the fields.

To correct for these incompleteness, we follow a similar method to that used in the PTF rates analyses of Frohmaier et al. (2019) and Frohmaier et al. (2020), outlined in Frohmaier et al. (2017). We simulate 1.1×10^6 SNe in the redshift range $0.05 \leq z_{\text{SN}} \leq 1.3$. The SNe are generated in the same way as for the training of SNN (Section 2.2.1). The SNe are simulated with explosion epochs t_0 uniformly distributed between two months before DES-SN began and two months after it finished in order to account for all SNe that could have been observed by DES-SN. We run mock versions of the DES-SN survey, using the exact cadence, conditions, and zero-points from the survey itself. All of the detected simulated SNe are passed through the light-curve fit of SALT2 (Betoule et al. 2014), as per the implementation in SNANA, and those that fail the light-curve cuts outlined in Section 2.2.1 are discarded. We are left with a fraction of the original simulated SNe, and that fraction is dependent on a combination of sky location, explosion epoch, redshift, stretch, and colour. The fraction of recovered SNe (the efficiency) is thus described by a five-dimensional surface. For the i th SN the efficiency $\eta_{\text{SN},i}$ in field F , exploding at time t_0 at redshift z , with stretch x_1 and colour c , is

$$\eta_{\text{SN},i}(F_i, z_i, t_{0,i}, x_{1,i}, c_i) = \left(\frac{N_{\text{obs}}(F_i, z_i, t_{0,i}, x_{1,i}, c_i)}{N_{\text{sim}}(F_i, z_i, t_{0,i}, x_{1,i}, c_i)} \right). \quad (1)$$

In practice, the gradient of the efficiency function is strongest between different DES fields and as a function of redshift, while SN stretch and colour have smaller effects. We integrate the efficiencies across the full simulated time range, and as such the efficiency is limited to ~ 0.5 due to the 6-month nature of the DES observing seasons. The distribution of efficiency as a function of redshift is shown in Fig. 2. It is evident that the deep fields (X3, C3) are

Figure 3. SN host galaxy spectroscopic efficiencies as a function of redshift z . Efficiency curves are grouped by shallow ($\{F\}12$) and deep ($\{F\}3$) fields, and averaged over the 5 yr of the survey. The lower and upper redshift limits for this analysis are indicated by z_{\min} and z_{\max} , respectively.

sensitive to SNe at higher redshifts, while there is no drastic shifts between efficiencies in the eight shallow fields. There is evidence that the SN efficiency depends weakly on x_1 and more strongly on c , which is expected since the colour-correction term is larger than the stretch correction term in the SN Ia standardization formula (Tripp 1998). Blue SNe are recovered more readily than red SNe as they are generally brighter.

The deep fields show non-zero efficiencies approaching $z = 1$, whereas the shallow fields typically reach $z = 0.8$. Since fractional uncertainty is large at such low efficiencies, we choose to make a redshift cut of $z = 0.6$ where the efficiency is well above 0.1 in all fields.

3.2 Supernova hosts

A further limiting factor in the SN host sample is the requirement of a spectroscopic redshift. The majority of SN host spectroscopic redshifts in DES are provided by the dedicated follow-up survey O z DES, for which the limiting magnitude is around 24 to 24.5 mag in the r band (Lidman et al. 2020). The rate at which a host redshift is successfully measured given an apparent magnitude has been extensively modelled by Vincenzi et al. (2020) who provide the spectroscopic redshift efficiency $\epsilon_{z_{\text{spec}}}(m_{r,i}^{\text{host}})$ as a function of host r -band magnitude, host galaxy colour, and the year in which the SN was discovered in order to allow for a longer possible spectroscopic exposure time for hosts of SNe discovered earlier in the survey. To assess how $\epsilon_{z_{\text{spec}}}(m_{r,i}^{\text{host}})$ translates into an efficiency as a function of redshift $\epsilon_{z_{\text{spec}}}(z)$ within the redshift limits of our survey, we use a simulation of host galaxies as described in Vincenzi et al. (2020). The simulation uses galaxy photometry from DES Science Verification images, and then selects them as potential SN hosts according a weighting driven by previously measured SN rate - host galaxy relationships. We note that this is for display purposes only, so the relationships built into the simulation are not propagated to the final rate measurements. For bins in redshift, we find the mean efficiency for measuring a spec- z of all galaxies in the bin via $\epsilon_{z_{\text{spec}}}(m_{r,i}^{\text{host}})$. The resulting $\epsilon_{z_{\text{spec}}}(z)$ curves are displayed in Fig. 3 and show a high spectroscopic efficiency within the redshift limits of this analysis.

The effects of the host galaxy spectroscopic efficiency are displayed in the upper panel of Fig. 1, where the normalized histogram weighted by the efficiency is skewed towards lower masses when compared to the unweighted distribution. So that we reduce any bias towards SNe in bright hosts that are easier to obtain spectroscopic redshifts for, the host galaxy spectroscopic redshift efficiency is multiplied by that derived from the SN detection efficiency (Section 3.1) to arrive at the final efficiency for the i th SN:

$$\eta_{\text{SN},i} = \eta_{\text{SN},i}(F_i, z_i, t_{0,i}, x_{1,i}, c_i) \times \epsilon_{z_{\text{spec}}}(m_{r,i}^{\text{host}}). \quad (2)$$

3.3 Field galaxies

3.3.1 Apparent magnitude limits

As we use photometric, rather than spectroscopic, redshifts for the field galaxies, they do not suffer from spectroscopic incompleteness as the SN hosts do. Instead, the inclusion of any given galaxy in the survey area in the sample is determined simply by whether it is detected above a prescribed threshold in SNR, i.e. the sample is magnitude-limited modulo the cuts described in Section 2.4. To determine the apparent magnitude limit for galaxies in each of the optical bands we employ the method of Johnston, Teodoro & Hendry (2007), Teodoro, Johnston & Hendry (2010), and Johnston, Teodoro & Hendry (2012) (hereafter Completeness I, II, III respectively). These works provide two complimentary statistics in order to find the limiting magnitude based on ranking of galaxies' absolute magnitudes in a given band M and distance moduli Z , named T_C and T_V , respectively. Galaxies are first placed in the $M - Z$ plane, which is limited to distance moduli that correspond to the redshift cuts $0.2 < z < 0.6$ introduced in Section 3.1. Each galaxy in the survey is ranked by its Z (M) compared to all other galaxies that fall within a slice of width δM (δZ) – we find that $\delta M = \delta Z = 0.02$ mag provides the best balance between high sampling resolution and an adequate number of galaxies within each slice. We then iteratively test different trial limiting apparent magnitudes $m_{\text{lim, trial}}$. For a galaxy of apparent magnitude $m < m_{\text{lim, trial}}$ observed in a survey complete to magnitude $m_{\text{lim, true}}$ where $m_{\text{lim, trial}} \leq m_{\text{lim, true}}$, the expectation value of the rank for a random is 0.5. However, if a trial limiting magnitude $m_{\text{lim, trial}} \geq m_{\text{lim, true}}$, there will be a lack of observed faint objects, such that the expectation value of the rank drops.

Completeness I, II, and III show that for surveys with sharp, well-defined magnitude limits the test statistics T_C and T_V are stable and flat as a function of apparent magnitude up until the magnitude limit, where they drop sharply. Fig. 4 shows the values of T_C and T_V in the DES X3 field. The values of the test statistics increase with $m_{\text{lim, trial}}$ until a peak, before decreasing to stable values at magnitudes far beyond the limit of the survey, contrary to the sharp drop in an ideal survey. The shape at brighter $m_{\text{lim, trial}}$ is likely caused by incompleteness at the bright end: due to the small sky area, we simply do not probe enough volume to sample the bright end of the galaxy luminosity function well enough for the statistics to be robust.

To approximate an efficiency function, we fit the peak of the statistics with a polynomial function, and then normalize by the maximum and minimum values. We then interpolate between the peak and the faint-magnitude floor to find the 50 per cent completeness limit at the point where the normalized value of the test statistic is 0.5. These values are consistent with the value at which 50 per cent of the true sources are detected but have the advantage of being derived from the data without a simulation that is based on assumptions and thus

Figure 4. Measuring the completeness of the field galaxy sample. Upper: the T_C galaxy completeness statistic (which is calculated by ranking objects by absolute magnitude in slices of distance modulus) as a function of apparent magnitude; middle: as per upper, but for the T_V statistic which is measured by ranking galaxies by distance modulus in slices of absolute magnitude; lower: the combined, normalized completeness in each band.

susceptible to bias. Our final limiting magnitude for each band is the mean of that found from each of T_C and T_V .

3.3.2 V_{\max} correction

To correct for incompleteness caused by the magnitude-limited nature of the survey we follow the prescription of Sullivan et al. (2006) and Smith et al. (2012) by using a V_{\max} method based on Schmidt (1968). For each galaxy in the sample we calculate the maximum volume within which it would have been observed given its absolute magnitude and k -correction, and the apparent magnitude limits calculated using the T_C and T_V statistics. A correction of $V_{\text{survey}}/V_{\max}$ is applied to all galaxies for which $V_{\max} < V_{\text{survey}}$, where V_{survey} is the maximum volume reached by the survey. In our case this corresponds to the volume at $z = 0.6$. Fig. 5 shows the distribution of the correction among galaxies in the sample. The vast majority of galaxies require no correction, meaning they would have been observed beyond the maximum volume considered. Roughly 1 per cent of objects have a correction greater than 1, with the distribution well described by a power-law function. The effect of the V_{\max} correction on the total galaxy counts in each stellar mass bin can be seen in Fig. 1; indeed, the two histograms are visibly indistinguishable above $10^9 M_{\odot}$ which indicates a sample that is effectively complete in this mass range in the redshift range of interest.

4 THE PER-GALAXY RATE OF TYPE IA SUPERNOVAE

The rate of SNe per galaxy (R_G) per year in a transient survey can be approximated by the equation:

$$R_G = \frac{N_{\text{SN}}}{N_G} \frac{V_G}{V_{\text{SN}}} \frac{1}{T}, \quad (3)$$

where N_{SN} and N_G are the respective numbers of SNe and galaxies detected, V_{SN} and V_G the volumes from which the SNe and galaxy samples were taken, and T the duration of the SN survey in years.

Figure 5. Distribution of V_{\max} corrections applied to field galaxies in the DES sample in order to correct for incompleteness. The majority of galaxies have no correction, and the distribution of those that do follows a power law.

As described in Section 3, the values of N_{SN} and N_G that we observe are underestimates of the true numbers due to observational incompleteness – we do not detect and count all SNe in the volume V_{SN} , nor do we detect and count all galaxies in the volume V_G . We thus estimate the intrinsic numbers of SNe and galaxies by multiplying the observed numbers by their respective incompleteness corrections calculated in Sections 3.1 and 3.2 for SNe and Section 3.3 for field galaxies:

$$N_{\text{SN},\text{intrinsic}} = \sum_i^{N_{\text{SN}}} \eta(F, z, t_0, x_1, c, m_r^{\text{host}})_i, \quad (4)$$

and

$$N_{G,\text{intrinsic}} = \sum_j^{N_G} \eta(V_{\max})_j \quad (5)$$

for each SN i and galaxy j . The volumes V_{SN} and V_G are calculated from the sky areas from which the respective samples were taken: 1.52 deg^2 in the case of the field galaxies (Hartley et al. 2020); 23 deg^2 for SNe (Smith et al. 2020a). These areas are combined with the redshift interval $[0.2, 0.6]$ to determine the total volumes.

By binning both the SN hosts and field galaxies by their stellar mass we measure the mean SN Ia rate per galaxy as a function of stellar mass, $R_G(M_*)$. We employ a bootstrap Monte Carlo approach in order to estimate the uncertainty in the value of the rate in each stellar mass bin. The probability density function (PDF) of each galaxy's stellar mass is represented by the sum of two half Gaussian distributions to represent the asymmetric positive and negative uncertainties derived in the SED fitting stage (Section 2). For each SN host and field galaxy, we take 100 samples of its stellar mass by drawing at random from its PDF. For each of the 100 samples we calculate the SN rate per galaxy in each stellar mass bin via equation (3), using the completeness-corrected values of N_{SN} and N_G from equations (4) and (5) respectively.

The rate of SNe Ia per galaxy as a function of stellar mass is shown in Fig. 6. The relationship between SN Ia rate and galaxy stellar mass is well described by a linear function in log space, which corresponds to a power law. To find the slope and intercept that best describe the data we use Bayesian inference. To sample the posterior we

Figure 6. The rate per galaxy of SNe Ia as a function of stellar mass. Horizontal error bars represent the width of the stellar mass bins. Vertical error bars are estimated via a Monte Carlo resampling of the rate given the uncertainties in stellar mass. The linear fit is based on all but the lowest and highest mass bins, and takes into account uncertainties in the rate.

use the enhanced no-U-turn Sampler (NUTS) algorithm (Betancourt 2017), which is a variant of Hamiltonian Monte Carlo (HMC), implemented in the Stan programming language (Carpenter et al. 2017). We describe the fitting procedure in full detail in Appendix A. We measure a slope of 0.63 ± 0.02 , which is consistent with the value found in weakly star-forming galaxies in the Supernova Legacy Survey by Sullivan et al. (2006), but also in passive galaxies in SDSS by Smith et al. (2012), and in all galaxies in the Lick Observatory Supernova Search (LOSS) by Li et al. (2011). Our slope is also consistent with that measured in the low-redshift All-Sky Automated Survey for Supernova (ASAS-SN) Bright Supernova Catalogues (Brown et al. 2019), which extends to galaxies with stellar mass as low as $10^7 M_\odot$.

A best-fitting slope of less than unity corresponds to a power law and indicates that SN Ia rate is not uniquely determined by host galaxy stellar mass. Indeed, the rate is instead likely to be driven by the DTD which is a nonlinear function of stellar age. Investigating the shape of this DTD forms the basis for the latter part of this paper in Sections 5 and 6. The straight line fit in Fig. 6 deviates somewhat from the central values of the data at high stellar mass, the reason for which we investigate in Section 5.4.

5 MODELLING THE PER-GALAXY RATE OF TYPE IA SUPERNOVAE

In Section 4 and Fig. 6, we showed that the SN Ia rate per galaxy as a function of stellar mass is approximated by, but not perfectly described by, a power law. In this section, we introduce a physical model in order to better fit the observed rate versus stellar mass relationship.

We begin by considering the delay time distribution of SNe Ia. We represent the SN Ia DTD by a power law, which we consider effective after some ‘prompt time’ t_p , before which its value is set to 0. t_p is generally interpreted as the time taken for WDs to form after the burst of star formation. The DTD is thus:

$$\Phi(\tau) = \begin{cases} 0, & \tau < t_p \\ A \left(\frac{\tau}{\text{Gyr}} \right)^\beta, & \tau \geq t_p \end{cases} \quad (6)$$

where τ is the time since a burst of star formation, and A is a normalization at $\tau = 1$ Gyr. If all stars in a galaxy were formed at a single epoch t_f , the DTD would describe the rate of SNe Ia at an observation time $\tau = t_0$. However in reality galaxies are formed by the gradual build-up of stellar mass over several epochs of star formation – the distribution of this mass build-up is known as the SFH. The rate of SNe Ia is thus the sum of the DTD evaluated for each epoch of star formation, multiplied by the stellar mass formed in that epoch. Mathematically this is represented by the convolution of the DTD and SFH:

$$R_G = \int_{t_0}^{t_f} \psi(t_0 - \tau) \Phi(\tau) d\tau, \quad (7)$$

where t_0 is the epoch at which the galaxy is observed, t_f is the time at which the first stars in the galaxy formed, and ψ is the SFH.

In previous work (e.g. Strolger et al. 2004; Maoz et al. 2012) it has been common to determine the SFH for every galaxy in the survey via SED fitting. Equation (7) is then used to calculate an expected number of SNe in each galaxy given the effective survey time, which is compared to the observed number in that galaxy (usually 0 and occasionally 1) using Poisson statistics. This method relies on either photometry covering several wavelength bands, or optical spectra with a high SNR, in order to distinguish accurately between SFHs. Such accuracy is not possible for the DES sample; we do not possess spectra of all galaxies in the field, and in some cases only have the four optical bands available – and have a maximum of eight from NUV to NIR – from which to infer an SFH. This lack of detail is compounded by our reliance on photometric redshifts, which add an extra layer of uncertainty to the calculation.

Instead of determining individual SFHs for each galaxy in our field sample, we use an empirical approach to estimate mean SFHs for galaxies as a function of their stellar mass at any given redshift (or equivalently, time t_0), that can be represented as $\hat{\psi}(t_0 - \tau; M_*)$. This method paves the way for modelling the SN Ia rate as a function of stellar mass by combining the mean SFHs and the DTD through equation (7), and thus placing constraints on the DTD.

5.1 Modelling the star formation histories of galaxies

To model the SFH of galaxies as a function of their stellar mass we adopt the prescription of stellar mass assembly of C14, which draws on the work of Zahid et al. (2012). In the model, galaxies are expected to evolve smoothly along the so-called ‘main sequence of star formation’ whereby the SFR of a galaxy of stellar mass M_* at redshift z is determined by a simple relationship (the SMz relation, Zahid et al. 2012). Specifically, we implement their ‘fine-tuned’ model (equation A7 in C14), whereby the SMz flattens above $z \sim 2$ in line with observations (Stark et al. 2013):

$$\Psi(M_*, z) = \left(\frac{M_*}{10^{10}} \right)^{0.7} \frac{\exp(1.9z)}{\exp(1.7(z-2)) + \exp(0.2(z-2))} \times [M_\odot \text{yr}^{-1}], \quad (8)$$

where M_* is given in units of M_\odot . As galaxies grow, their SFR begins to slow down and eventually shut off almost entirely in a process known as quenching. We adopt the quenching penalty p_Q directly from C14:

$$p_Q(M_*, z) = \frac{1}{2} \left[1 - \text{erf} \left(\frac{\log(M_*) - \log(M_Q(z))}{\sigma_Q} \right) \right], \quad (9)$$

where $M_Q(z)$ describes how the quenching mass evolves with redshift, and σ_Q is the transition scale which controls how fast a

galaxy quenches. We adopt the observationally motivated form of the quenching mass evolution (equation A8 from C14):

$$\log(M_q(z)/M_\odot) = 10.077 + 0.636z, \quad (10)$$

and a transition scale of $\sigma_Q = 1.1$ which provides a good fit to data from the Galaxy And Mass Assembly (GAMA) survey (Baldry et al. 2012).

Finally, at time t , some time τ since an epoch of star formation, a fraction of stellar mass is lost. We adopt the parametrization used by C14, namely that of Leitner & Kravtsov (2011) for a Chabrier (2003) IMF:

$$f_{\text{ml}} = 0.046 \ln \left(\frac{\tau}{0.276 \text{ Myr}} + 1 \right). \quad (11)$$

The mass loss at any given time is thus the convolution of the equations (8) and (11):

$$\Delta M_* = \int_0^{t_f} \Psi(M_*(t - \tau), z(t - \tau)) \cdot (f_{\text{ml}}(\tau + \Delta t) - f_{\text{ml}}(\tau)) d\tau. \quad (12)$$

The stellar mass formed in each time t (and corresponding redshift z) is thus the combination of the mass- and redshift-dependent SFR (equation 8), reduced by the mass- and redshift-dependent quenching penalty (equation 9), minus the mass lost in each time-step (equation 12):

$$\frac{M_*(t + \Delta t) - M_*(t)}{\Delta t} = p_Q(M_*(t, z(t)) \cdot \Psi(M_*(t), z(t)) - \frac{\Delta M_*}{\Delta t}. \quad (13)$$

As per C14 we plant seed galaxies with initial masses of $10^6 M_\odot$ at intervals of 50 Myr for look-back times $1 \text{ Gyr} \leq t_f \leq 10 \text{ Gyr}$, and 25 Myr for look-back times $10 \text{ Gyr} \leq t_f \leq 13 \text{ Gyr}$ to achieve a more detailed model at early times with high SFR. For each seed galaxy, we evaluate equation (13) at time-steps of 0.5 Myr and record the total mass formed and lost in each of the time-steps – this defines our model SFH to be used as input to equation (7).

The result of our toy model is shown in Fig. 7. Galaxies with high masses at $z = 0$ formed the vast majority of their stars in the first few Gyr and are now likely to be passive with old stellar populations, while low-mass galaxies are currently strongly star-forming with a vast majority of young stars. Galaxies with masses around $10^{10} M_\odot$ are composed of a mixture of young and old stellar populations.

5.1.1 Validating the mass assembly model

As noted in C14, this toy model by construction follows several empirical relations derived from galaxy observations: model galaxies follow the SMz relation and obey quenching prescriptions motivated by observed galaxies. Here we make two further checks to validate that the model can be used to approximate the stellar age distribution of SN Ia host galaxies in DES.

First, we follow C14 by summing our SFHs and weighting by the galaxy stellar mass function at $z = 0$ to estimate the CSFH. We approximate the present-day stellar mass function according to a double Schechter function with parameters from the Galaxy and Mass Assembly survey Baldry et al. (2018): $\log(M^*/M_\odot) = 10.66$, $\phi_1^* = 3.96 \times 10^{-3}$, $\alpha_1 = -0.35$, $\phi_2^* = 0.79 \times 10^{-3}$, $\alpha_2 = -1.47$. The comparison of our approximate CSFH with that measured from observations (Madau & Dickinson 2014) is shown in Fig. 8. As was found in C14, the two functions show a good qualitative agreement – in fact, we find a closer match between the model and observed

CSFH, accurately reproducing the peak of cosmic star formation around $z \sim 2$ and tracing the declining SFR to the present day.

Secondly, we assess the shape of our SFHs and how they depend on stellar mass by comparing with SFH measurements from the Calar Alto Legacy Integral Field spectroscopy Area survey (CALIFA) as revealed by González Delgado et al. (2017). Our models agree qualitatively on numerous features of the SFHs (their Fig. 5): high-mass galaxies form almost all their stars at high redshift; intermediate-mass galaxies display a plateau in their SFR from ~ 4 Gyr to the present day; low-mass galaxies show an increasing rate of star formation at $z = 0$. The main discrepancy with the lowest-mass bin of the CALIFA sample $8.6 < \log(M_*/M_\odot) < 9.8$, which as well as an increasing SFR at low redshift shows a second peak of star formation at large look-back times, which we do not see in our model. However, this mass bin spans over one order of magnitude in stellar mass. Upon closer inspection of our model, the lower edge of this mass bin corresponds to galaxies that form at a look-back time of 5 Gyr and display a rising SFH. At the upper edge, galaxies do indeed form at times > 10 Gyr and display an early peak followed by exponential decline. The combination of these different model SFHs in the low-mass bin thus explain the dual-peaked nature of the observed SFHs in CALIFA.

5.2 Constraints on the SN Ia delay time distribution

At the beginning of this section, we showed how the rate of SNe Ia is driven by the convolution of the SFH of galaxies and the SN Ia DTD (equation 7). We then prescribed a model to infer the mean SFHs of galaxies of any given stellar mass. Here, we measure the DTD by forward modelling it through equation (7) at the stellar masses corresponding to the centres of the bins in Fig. 6.

We assume a DTD $\Phi(\tau)$ with a power-law form described by index β (equation 6), normalization A and effective after prompt time t_p . As per Section 4, we constrain the parameters via Bayesian inference, using HMC to explore the posterior distribution. At each step of the sampling procedure the model is re-calculated via equation (7), we evaluate the likelihood assuming that the rate measurements R_{G, M_*} are described by a Gaussian PDF with mean \hat{R}_{G, M_*} and standard deviation $\sigma_{R_{G, M_*}}$. For β we adopt a Gaussian prior with hyper-parameters $p(\beta) \sim \mathcal{N}(-1, 0.5)$. We fit for A in log space, and adopt a Gaussian prior (in log space) with hyper-parameters $p(\log(A)) \sim \mathcal{N}(-12.7, 0.5)$.

SNe Ia do not occur instantaneously after an episode of star formation. Instead stars with zero-age main-sequence (ZAMS) masses less than $8 M_\odot$ take time to evolve along the main sequence and form WDs and this time is not well constrained. In many works this ‘prompt time’ which we denote t_p is fixed to some value expected to be the minimum time for a star to evolve off the main sequence and become a WD, such as 40 Myr (Maoz et al. 2012; Graur & Maoz 2013; Graur et al. 2014b). Other studies have left t_p as a free parameter (Heringer, Pritchett & van Kerkwijk 2019; Castrillo et al. 2020). We perform three fits: one with t_p fixed at 40 Myr, one with it as a free parameter along with β and A , and a third with β and A fixed and t_p free. We fit t_p in log space and adopt a Gaussian prior with hyper-parameters $p(\log(t_p)) \sim \mathcal{N}(-1.3, 0.5)$, which corresponds to being centred around 50 Myr. Choosing this regime to fit allows more prior weight to be placed on shorter prompt times as per the majority of the literature. We use the \hat{R} diagnostic of Vehtari et al. (2019) to assess the convergence of MC chains. When including t_p as a free parameter, we find that the strong degeneracy between t_p and A cause the sampler to fail to converge with $\hat{R} \sim 1.3$ for the chains of those two parameters. In

Figure 7. The stellar mass assembly of the Universe as prescribed by the toy model of C14. The y-axis is the fraction of a galaxy’s total mass of formed stars that are formed in each time bin. Galaxies with high stellar mass at $z = 0$ formed the majority of their stars in the distant past, while lower-mass galaxies are still actively star forming in the present day.

Figure 8. Cosmic star formation history (CSFH) as approximated by our model (cyan solid) and as a best fit to observations (magenta dashed; Madau & Dickinson 2014).

Figure 9. Posterior distributions for DTD slope β and normalization A . Displayed point estimates represent the median of the posterior samples.

subsequent analyses we adopt as our fiducial model that with fixed $t_p = 0.04$ Gyr.

The joint and marginal posterior distributions for the fit parameters are found in Fig. 9, and the posterior means and standard deviations are summarized in Table 2. Fig. 9 shows that there is a mild correlation between β and A . In Fig. 10, we show the SN rate per galaxy predicted by the model assuming the best-fitting DTD parameters from Table 2 compared to the data as presented in Section 4. Visually, the model provides a good fit across a wide range of stellar mass. The model clearly diverges from the simple

Table 2. Results of the Bayesian parameter estimation for the SN Ia DTD.

| | β | A $10^{-13} M_{\odot}^{-1} \text{yr}^{-1}$ | t_p Gyr |
|------------------|-------------------------|---|---------------------------|
| Fixed t_p | $-1.13^{+0.04}_{-0.06}$ | $2.11^{+0.05}_{-0.12}$ | – |
| Fixed A, β | – | – | $0.047^{+0.008}_{-0.007}$ |

Figure 10. Rate per galaxy of SNe Ia as a function of stellar mass (green points) along with the prediction from the best-fitting DTD parameters β , A , and t_p forward modelled through equation (7). Samples from the posterior distribution of the model log rate are drawn in cyan while the black dashed line is the mean of the posterior. In red we show the simple log-linear fit from Section 4.

log-linear fit, describing better the enhanced rate around $10^{10} M_{\odot}$ and suppression at high masses. This improvement provides evidence to support the DTD*SFH model. However, the model prediction still diverges from the data at high stellar masses ($>10^{11.25} M_{\odot}$), suggesting that these data cannot be explained by our model, but are driven by further processes that we have not included. We discuss these in Section 5.4.

5.3 Comparison to previous DTD measurements

5.3.1 The DTD power-law index

We measure a DTD power-law index of $-1.13^{+0.04}_{-0.06}$. This value is consistent with the majority of previous analyses using various methods. Our measurement provides an independent support to the values close to -1 found using volumetric rates (e.g. Graur et al. 2011, 2014b; Frohmaier et al. 2019), individual galaxy SFHs (e.g. Maoz et al. 2012; Graur & Maoz 2013), and galaxy clusters (e.g. Maoz et al. 2010) although our slope is marginally inconsistent with that of Heringer et al. (2019). The result is also qualitatively consistent with that of Strolger et al. (2020) who fit an exponential function DTD rather than a power law. However, their best-fitting model indicated a higher SN rate at long delay times than a τ^{-1} DTD, which is opposite to the mild preference of our fit which is steeper and thus produces a smaller fraction of SNe at long delay times.

5.3.2 The DTD normalization

We measure a DTD normalization (i.e. the rate of SNe 1 Gyr after star formation) of $2.11^{+0.05}_{-0.12} \times 10^{-13} M_{\odot}^{-1} \text{ yr}^{-1}$. Graur & Maoz (2013) found a value of $0.7 \times 10^{-13} M_{\odot}^{-1} \text{ yr}^{-1}$ using the SFH technique, whereas Heringer et al. (2019) report $7 \times 10^{-13} M_{\odot}^{-1} \text{ yr}^{-1}$. These results lie either side of our measured value. Heringer et al. (2019) note that the normalization recovered from the SFHR method is degenerate with the assumed prompt time t_p , a degeneracy that is also reflected in the non-convergence of our fit that included t_p as a

free parameter. The normalization is also sensitive to the assumed IMF which can explain this variation (Maoz & Graur 2017).

By integrating the normalized DTD over cosmic time, we obtain an estimate of the average SN Ia efficiency N_{Ia}/M_* which represents the number of SNe Ia formed per unit mass of stars formed. We measure $N_{\text{Ia}}/M_* = 0.9^{+4.0}_{-0.7} \times 10^{-3} \text{ SNe } M_{\odot}^{-1}$, which is consistent with Graur et al. (2011), Maoz et al. (2011), Perrett et al. (2012), and Graur & Maoz (2013)

5.3.3 The SN Ia prompt time

The majority of works in the field have constrained the DTD power-law slope, and many also estimate its normalization. Conversely, few have attempted to constrain the prompt time t_p . In most cases, t_p has been fixed at some fiducial value such as 40 Myr, which is derived from the lifetime of $8 M_{\odot}$ stars. Castrillo et al. (2020) included t_p (which they denote Δ) in their fit, and find a value of 50^{+100}_{-35} Myr which is consistent with both 40 Myr. While we are unable to fit t_p simultaneously with β and A , by fixing $\beta = -1$ and $\log(A) = -12.75$ we find $t_p = 47^{+8}_{-7}$ Myr, which is consistent with the fiducial value of 40 Myr. Heringer et al. (2019) also present fits with varying prompt times, although they don't fit for the parameter itself. They find that varying t_p changes the recovered normalization, which is consistent with the degeneracy encountered in our fits. Overall, we conclude that there is no strong evidence for a value of t_p that is different to the fiducial value of 40 Myr and adopt this value for the remainder of the analysis.

5.4 Second order processes affecting the supernova rate

The use of SN Ia rate measurements to constrain the SN Ia DTD has consistently led to a t^{-1} power law, which is widely accepted as evidence supporting the DD scenario. While our results are also consistent with those derived in previous studies, our model is mildly inconsistent with the SN rate per galaxy at very high stellar mass. The model over predicts the observed rate of SNe Ia in galaxies in that stellar mass range, caused either by a miscalculation of the rate or second-order effects acting to suppress the rate compared to the fiducial model.

5.4.1 Simplifications in the galaxy evolution model

The toy model of stellar mass assembly used in this work includes several assumptions about the evolution of galaxies. In particular, it is assumed that galaxies evolve independent of each other, growing up the star formation main sequence until they reach a mass at which they quench and star formation ceases. While these simplifications describe the average properties of galaxies well (Zahid et al. 2012; C14), they struggle to describe the more stochastic nature of galaxy evolution that occurs at the low- and high-mass ends: starbursts and quenching episodes, respectively.

At some point along the evolutionary pathway, galaxies begin to cease star formation due to a combination of processes that together are known as quenching. In our model of mass assembly the characteristic mass at which quenching occurs is described by equation (10), and the rate of the transition from star forming to passive (as a function of the stellar mass) is determined by the transition scale σ_Q which we set to 1.1 based on GAMA observations. It is possible that this transition is too narrow and that quenching happens too fast in our model, leading to an underprediction of the prompt fraction of SNe in the highest mass galaxies. To address this

issue we rerun the mass assembly model with $\sigma_Q = 1.5$ as per the nominal analysis of C14 and refit the SN Ia rate data. We find that the adapted quenching model does not result in a better fit to the high-mass turnover in the SN rate.

5.4.2 Effects of stellar metallicity

One possible cause of the discrepant SN Ia rate at high stellar mass is the effect of stellar metallicity. Metallicity has been previously invoked to explain irregularities or divergences from the fiducial DTD (e.g. Strolger, Dahlen & Riess 2010; Meng, Li & Yang 2011; Kistler et al. 2013). Metallicity may affect the observed rate of SNe in two ways: first, it can affect the time taken for a star to evolve along the main sequence (t_{MS}) – Stellar metallicity has varying effects on the main-sequence lifetime of stars (e.g. Georgy et al. 2013; Amard & Matt 2020), which is also dependent upon initial rotation and degree of mixing; secondly it can affect the time taken from WD formation to SN Ia explosion – low metallicity stars should produce higher-mass WDs (e.g. Umeda et al. 1999; Marigo & Girardi 2007), resulting in a higher SN Ia rate (Kistler et al. 2013), although note that Kistler et al. (2013) did not find any evidence for this in the data. Graur et al. (2017a) also found that evolution of SN Ia rates with metallicity is consistent with a DTD of the form τ^{-1} .

The mass-metallicity relation (MZR) is a strong observed correlation between galaxy stellar mass and gas-phase metallicity (e.g. Tremonti et al. 2004), whereby higher mass galaxies have undergone more cycles of stellar evolution and have been polluted with heavy elements created in stars and released in SNe. Thus, the mass of a host galaxy is inextricably linked to the metallicity of its hot gas. However, the nature of the DTD complicates matters, since stars of different ages were formed at different epochs where the galaxy had a different stellar mass and thus different metallicity. Therefore, there is not a direct correlation between the metallicity of SN Ia progenitors and their observed host galaxy stellar mass. This caveat notwithstanding, it may be an expected consequence of the stipulations of e.g. Kistler et al. (2013) that the rate of SNe Ia is suppressed in the highest mass galaxies where the metallicity is highest, as is the case in our data.

5.5 Rate per unit stellar mass

An alternative view on how the SN Ia rate relates to environment can be gained by calculating the rate of SNe per year per unit stellar mass: SNum. A measurement of the SNum is achieved by summing the number of SNe in each stellar mass bin, and dividing by the total stellar mass of field galaxies in that bin. We show the SNum as a function of galaxy stellar mass in Fig. 11, along with the measurements from SNe discovered in SDSS spectra (Graur & Maoz 2013) at $z \sim 0.1$ and at $z \sim 0$ in LOSS as presented in Li et al. (2011). We also calculate the SNum predicted by our model for each simulated galaxy at a range of redshifts and plot these as curves in Fig. 11. Our model accurately recovers the SNum measured in DES for the redshift and stellar mass range of the data. While the data from LOSS and SDSS spectra lie slightly higher than our model prediction, the difference is consistent with differences in assumed SFHs, IMFs and stellar population templates as well as SN detection method. Any true residual difference between predicted and observed SNum at different redshifts could be caused by an evolution of the SN Ia production efficiency as a function of redshift; we defer such an investigation to future work with more refined models and measurements.

There is tentative evidence in the data for a flattening of the SNum versus stellar mass at $\log(M/M_\odot) \leq 9.5$, which is broadly predicted

Figure 11. SN Ia rate per unit stellar mass as function of galaxy stellar mass. Error bars are the same as Fig. 6. Literature data are that from SDSS spectra (orange squares; Graur & Maoz 2013) and the LOSS sample (grey dotted; Li et al. 2011). The systematically higher SNum in DES is caused by the higher redshift of the sample, as illustrated by the prediction of the model using our best-fitting DTD from Section 5.2 (coloured curves).

by the model and is qualitatively consistent with the shape of the analytic fit of Kistler et al. (2013) while standing in slight tension with the conclusions of Brown et al. (2019). The uncertainty of the measured rates at these low stellar masses prevents us from drawing further conclusions at this stage.

6 THE DELAY-TIME DISTRIBUTION AS A FUNCTION OF SUPERNOVA PROPERTIES

In the previous sections we considered all SNe that passed the various quality, standardization, and redshift cuts. However, it is well established that SNe Ia show correlations of varying strength between properties of their light curves and host galaxies. For example, it is well established that measures of the light-curve duration (e.g. decline rate, or stretch such as SALT2 x_1) correlate with host galaxy properties such as morphology (Hamuy et al. 1995, 2000; Mannucci et al. 2005), stellar mass (Kelly et al. 2010; Lampeitl et al. 2010; Sullivan et al. 2010) and specific SFR (Rigault et al. 2013, 2020). If such correlations are caused by intrinsic differences in the progenitors or their surroundings, there may be signatures in the DTDs of SNe when divided into smaller samples. Such a hypothesis was investigated by Brandt et al. (2010) who found evidence for differing DTDs for SNe of low and high stretch, although Perrett et al. (2012) found no evidence for a change in volumetric rate evolution (expected due to the evolution of the CSFR) for the same stretch split. In this section, we split the DES SNe Ia by their stretch and colour, and assess how the measured rates and DTDs vary across this parameter space. To do so we split the sample into subsamples with $x_1 = 0$ and $c = 0$ as the divisions points respectively. We repeat the analyses of Sections 4 and 5 including all of the previous light-curve cuts, performing the DTD fitting with a fixed $t_p = 40$ Myr, and present the results in Table 3. Posterior distributions for fitted parameters are presented in Appendix B.

6.1 Splitting by SN stretch

The SN Ia rate as a function of stellar mass for SNe split by stretch is shown in Fig. 12. The evolution of the rate with stellar mass

Table 3. Results of the Bayesian parameter estimation for the SN Ia DTD.

| Sample | β – | A $10^{-13} M_{\odot}^{-1} \text{yr}^{-1}$ |
|-----------|-------------------------|---|
| Fiducial | -1.13 ± 0.05 | 2.11 ± 0.08 |
| $x_1 < 0$ | -0.79 ± 0.08 | 1.19 ± 0.05 |
| $x_1 > 0$ | $-1.70^{+0.19}_{-0.10}$ | $0.50^{+0.26}_{-0.09}$ |
| $c < 0$ | $-1.11^{+0.05}_{-0.11}$ | 0.90 ± 0.04 |
| $c > 0$ | -1.18 ± 0.09 | $1.14^{+0.11}_{-0.05}$ |

**Figure 12.** As per Fig. 10, but with the data split by their stretch parameter x_1 . Fits were performed with the DTD slope β and normalization A as free parameters, and prompt time t_p fixed at 0.04 Gyr.

is significantly different for the two subsamples: high-stretch SNe dominate the rate at low stellar mass but tail off in the higher mass galaxies, while low-stretch SNe are subdominant in low-mass galaxies but display a much steeper dependence on stellar mass and make up the vast majority of SNe in high-mass hosts. These measurements reflect the observed correlations of x_1 with stellar mass, sSFR (and by inference, stellar age) as been seen by Rigault et al. (2013), Graur et al. (2017b), Rigault et al. (2020), Rose et al. (2019), Hakobyan et al. (2020), Nicolas et al. (2021), Rose et al. (2021), as well as morphology (Hakobyan et al. 2020). The corresponding DTD fit results in a steep power law $\beta = -1.70^{+0.19}_{-0.10}$ for high-stretch SNe indicative of a population of pre-dominantly prompt SNe, and a much shallower decay slope ($\beta = -0.79 \pm 0.08$) for low-stretch SNe representing a much more delayed population. The difference in β is significant at a level of 3.8σ . This result provides an intriguing confirmation of that observed in 101 SDSS SN Ia by Brandt et al. (2010) who found that low- x_1 SNe displayed much longer delay times than those with high x_1 .

From the differing DTDs that describe SNe with low and high stretch values we infer that there are either multiple channels through which SN Ia explode which occur on differing time-scales (as discussed in Hakobyan et al. (2020)), or that the explosion mechanism evolves with progenitor age. Two scenarios, that are not necessarily mutually exclusive, that could lead to different DTD decay rates are as follows. The first such scenario is to assume that all SN Ia come from the same initial population of stars, and thus that the progenitors of both low and high stretch SNe form at the same time. It is then necessary to invoke models in which the WD

progenitors of low-stretch SNe evolve on longer time-scales than those of high-stretch SNe, for example due to a different initial binary separation distribution or accretion rate. In this case, the DTD slopes would indeed take on the different values measured here.

Alternatively, low- and high-stretch SNe could form via identical evolutionary channels but with a different onset time since the episode of star formation. In this scenario, the pre-dominantly high-stretch ‘prompt’ SNe begin exploding as soon as the WDs are formed (nominally 40 Myr) whereas the mainly low-stretch ‘tardy’ SNe only begin exploding after an extended period of time of the order 1 Gyr. The time dependence of both populations would follow the fiducial τ^{-1} distribution. Such a scenario may be explained by the sub- M_{Ch} double-detonation paradigm (e.g. Sim et al. 2010; Blondin et al. 2017; Shen et al. 2017). Sub- M_{Ch} SNe Ia typically involve the merger of two WDs and the SN luminosity can be correlated with the mass of the primary WD; a correlation between primary WD mass and age leads to different DTDs of low and high-stretch SNe and hence the different rates observed in this work. Such an evolution of light-curve properties with age has recently been seen across the full range of ‘normal’ SNe Ia in one-dimensional simulations by Shen et al. (2021) and is a promising avenue for further investigation although we note that they struggle to reproduce observed light curves at later times ($t \gtrsim 30$ d; Gronow et al. 2021; Shen et al. 2021).

We explore this scenario by fitting the stretch-separated subsamples with modified DTDs. We fix the DTD to a power law with index -1 , and fix the normalization to the best-fitting value from the full sample. We model the DTD as comprising two components: the prompt, high-stretch SNe and the tardy, low stretch SNe, and we introduce two time-scales, t_1 and t_2 . At $\tau \leq t_1$, the DTD is caused solely by prompt SNe; at $\tau \geq t_2$ only tardy SNe explode. In between where $t_1 \leq \tau \leq t_2$, the DTD is a sum of DTD (prompt) and DTD (tardy), where we model the relative fraction f as a smooth linear slope between t_1 and t_2 :

$$f_{\text{tardy}} = \frac{\tau - t_1}{t_2 - t_1}, \quad (14)$$

and

$$f_{\text{prompt}} = 1 - f_{\text{tardy}}. \quad (15)$$

With β and A fixed, we fit the split- x_1 SN Ia rate with t_1 and t_2 as free parameters, and weak normal priors $p(t_1) \sim \mathcal{N}(0.5 \text{ Gyr}, 0.5 \text{ Gyr})$ $p(t_2) \sim \mathcal{N}(1 \text{ Gyr}, 0.5 \text{ Gyr})$ and the constraint $t_2 > t_1$.

The SN Ia rates generated by the posterior predictive checks are shown in Fig. 13. The best-fitting values are mildly consistent with one another, with $t_1 = 0.69^{+0.07}_{-0.13}$ Gyr and $t_2 = 0.81^{+0.13}_{-0.10}$ Gyr, corresponding to a relatively sharp transition between the two populations. Our t_1 and t_2 are reminiscent of the transition found by Brandt et al. (2010) who found high-stretch SNe to be confined to delay times $\lesssim 0.4$ Gyr while low-stretch SNe occurred with delay times $\gtrsim 2.4$ Gyr. The transition found in our analysis appears to occur at much shorter delay times than the several Gyr found by Rose et al. (2019). These results are somewhat surprising, as we might expect that the transition is not so sharp but a gradual correlation of delay time with the average stretch of SNe caused by the age versus WD-mass distribution, as predicted by Shen et al. (2021). However we note that the intrinsic stretch distribution may not be a simple Gaussian, but could instead be bimodal (Scolnic & Kessler 2016; Nicolas et al. 2021; Popovic et al. 2021). The correlation of progenitor age and WD mass does not easily reproduce such a bimodal distribution, which may suggest that the sub- M_{Ch} channel cannot account for all SN Ia. We also note that our method models the average SFH of galaxies and that the DTD is a statistical distribution: our results do not rule out high-stretch

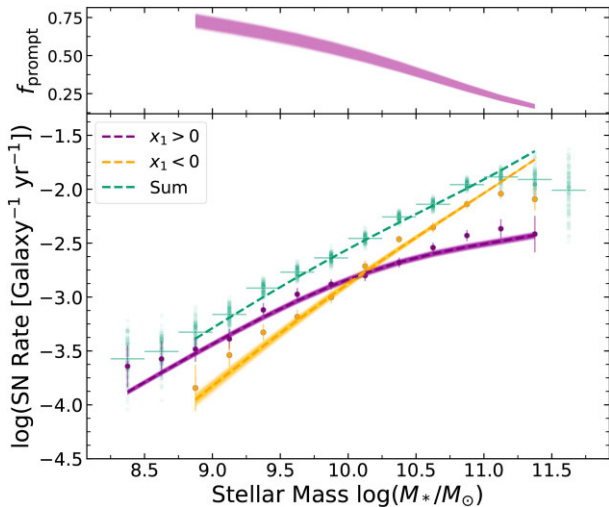

Figure 13. Upper: Posterior samples of the fraction of ‘prompt’ SNe resulting from the two-population fit, displayed as a function of host galaxy stellar mass. Lower: As per Fig. 12, but with the data fit simultaneously by a single two-component DTD, with fixed slope $\beta = -1$ and a prompt fraction that is 1 at short delay times, 0 at large delay times, and a linear function of time between $t_1 = 0.65$ Gyr (where tardy SNe switch on) and $t_2 = 0.85$ Gyr (where prompt SNe turn-off).

SNe arising from old progenitors, but suggest that such a scenario is unlikely.

6.1.1 The late end of the DTD

Despite the reasonable fit of the evolving population model, the fit to tardy SNe diverges from the data at high stellar mass, corresponding to the oldest average stellar age. It is difficult to reconcile this turnover with the simple DTD models used thus far in this work, as it would require a steepening or complete turn-off of the DTD at late ($\tau \gtrsim 5$ Gyr) times.

One possibility is that subluminal SNe are more numerous in pre-dominantly old stellar populations, such that the fraction passing our light-curve cuts is lower than the rest of the sample. Such a phenomenon could be caused by SN Ia subclasses such as SN 1991bg-like SNe, which are known to explode exclusively in old environments (Perets et al. 2010; Barkhudaryan et al. 2019) at delay times as long as >6 Gyr (Panther et al. 2019), and are typically subluminal with low stretch (González-Gaitán et al. 2014). If the SN 1991bg-like objects are drawn from the same parent population of WDs as the ‘normal’ SNe Ia, their presence in high-mass hosts could explain the apparent lack of normal SNe Ia in the sample. We check this hypothesis briefly by re-examining the objects left out of our sample due to SALT2 cuts. We find that 75 per cent of objects left out lie in hosts with $M_* > 10^{10} M_\odot$, while this percentage is 65 per cent for the objects that pass the cuts. However, of the objects in high-mass galaxies that fail the cuts, only 11 (10 per cent) fail due to their x_1 lying below -3 , and a total of 20 have $x_1 < -2$ which is the regime populated by SN 1991bg-like objects which is well short of the factor of two by which the DTD model overpredicts the data in the highest mass bin. Another issue is that SN 1991bg-like SNe are generally fainter than normal SNe Ia and the massive galaxies in which they explode are typically bright, leading to a lower detection efficiency than that modelled in Section 3.1. A thorough investigation into the presence of SN Ia subtypes in the DES-SN data set is deferred to a future investigation.

Figure 14. As per Fig. 12, but with the data split by their colour parameter c .

6.2 Splitting by SN colour

In the previous section, we showed that the slope of the SN Ia rate versus stellar mass relation is different for slow and fast declining supernovae. We find no evidence for a similar difference between SNe with different colours (Fig. 14), with best-fitting values of β of -1.19 ± 0.09 and -1.09 ± 0.08 for red ($c > 0$) and blue ($c < 0$) SNe respectively. This consistency is in agreement with the findings of Sullivan et al. (2010). Red SNe appear to have a higher normalization than blue SNe, with roughly 30 per cent more red than blue SNe. This dominance can be explained by a single population of SNe with an intrinsic colour distribution that is Gaussian and centred on $c = 0$ combined with an external dust distribution with an exponential form, systematically shifting the SN colour distribution to the red and causing the higher observed rate of those objects. Such a scenario has been implemented previously in the Multicolor Light-curve Shapes framework (Riess, Press & Kirshner 1996; Jha, Riess & Kirshner 2007), and recently explored in detail by Brout & Scolnic (2021).

In Fig. 14, the predictions from the DTD model differ from the data at low stellar mass ($\log(M_*/M_\odot) < 9.25$). Here, the model predicts that red SNe should dominate at the same level as across the full mass range, and the relative difference should remain. The data however become dominated by blue SNe. Although this is where the data is noisiest due to the low number of SNe, it is worth investigating the possible causes of this divergence. A slight preference for SN to be bluer in lower-mass galaxies has been observed (Scolnic et al. 2018; Brout et al. 2019; Smith et al. 2020b; Kelsey et al. 2021) and could be the same effect seen at low stellar masses here. Physically, the dominance of blue SNe at low stellar masses could either be an intrinsic property of the SNe such as a hotter photosphere in explosions of younger, more massive progenitors, or an extrinsic effect such as a lower average dust column density in low-mass host galaxies. An intermediate explanation is that the SNe in low-mass hosts have a smaller dust column density in the immediate vicinity of the progenitor system, either due to the shorter evolutionary time-scale or the higher mass and thus brighter system being less conducive to dust production. A detailed exploration of the effects of environment on SN colour in the DES-SN photometric sample will be presented in Kelsey et al. (in preparation).

7 CONCLUSIONS

Here, we summarize the key findings presented in this paper:

(i) We have measured the rate of SNe Ia per galaxy based on a sample of over 800 SNe and 40 000 galaxies detected by DES. We find a tight linear relationship between SN rate and galaxy stellar mass as seen in SNLS (Sullivan et al. 2006) and SDSS (Smith et al. 2012) and constrain the slope to high precision. The power-law slope of 0.63 being less than unity indicates that the rate of SNe is not solely driven by stellar mass, but also other factors such as the SFH.

(ii) By simulating the stellar mass assembly of average galaxies across cosmic time following the prescription of C14 we have recovered an estimate of the SN Ia DTD, finding a good fit to a power-law distribution with an index of -1.14 ± 0.05 . Our measurement of the DTD provides a further tight constraint to those of previous measurements (e.g. Graur & Maoz 2013; Maoz & Graur 2017) and carries signatures predicted by the DD scenario for SNe Ia production.

(iii) We find strong differences in the slope of the SN rate versus stellar mass between SNe with low- and high-stretch factors (3.6 σ). The differing slopes are readily explained by the correlation between stretch and stellar age, since more massive galaxies play host to older stellar populations which are known to give rise to lower-stretch SNe

(iv) Further investigations of low- and high-stretch SNe reveal two plausible scenarios causing the observed relations. First, low- and high-stretch SNe could belong to separate populations with different DTD slopes, resulting from a different set of initial conditions such as binary separation at the epoch of WD formation. Alternatively, SNe Ia could follow a single DTD where the relative composition of low- and high-stretch objects could change over time. We find a relatively sharp transition at delay times between 0.65 and 0.85 Gyr. Such a scenario is compatible with stretch being related to progenitor mass, a paradigm consistent with a sub- M_{Ch} double-detonation explosion mechanism.

(v) Red ($c > 0$) SNe explode at a higher rate than blue SNe at all mass ranges, we find that DTD decay slope is independent of SN colour. We assume that the higher rate of red SNe is caused by the addition of dust to an intrinsically Gaussian colour distribution centred slightly bluewards of $c = 0$, but defer a detailed investigation to future work.

SOFTWARE

All software used in this publication are publicly available. In particular, we made extensive use of `numpy` (Harris et al. 2020), `Astropy` (Astropy Collaboration 2013, 2018), `matplotlib` (Hunter 2007), `SciPy` (Virtanen et al. 2020), `pandas` (McKinney 2010), `Stan` (Carpenter et al. 2017), `seaborn` (Waskom et al. 2020), and `ChainConsumer` (Hinton 2016).

ACKNOWLEDGEMENTS

We thank J. Michael Burgess for discussions regarding model fitting in Stan. We thank the reviewer, Mickael Rigault, for constructive comments on the manuscript.

DATA AVAILABILITY

The DES-SN photometric SN Ia catalogue and associated host galaxy data will be made available as part of the DES5YR SN cosmology

analysis at <https://des.ncsa.illinois.edu/releases/sn>. Field galaxy data including photometric redshifts will appear alongside other data products released as part of the DES Y3 weak-lensing cosmology analysis at <https://des.ncsa.illinois.edu/releases>.

APPENDIX A: LINEAR FITS USING BAYESIAN INFERENCE

In this appendix, we describe the procedures used to fit slopes and intercepts to the relationships measured in the analysis.

We model the relation with the linear relationship:

$$R_G = \frac{dR}{dM_*} M_* + c, \quad (\text{A1})$$

where dR/dM_* signifies the change of the rate of SNe as a function of the stellar mass, c is a constant that sets the normalization of the rate. We fit the model assuming a normal likelihood, such that the observed rate in each stellar mass bin is itself modelled as a Gaussian distribution described by the mean and standard deviation of the data in that bin. We adopt weakly informative normal priors on the slope and intercept: $p\left(\frac{dR}{dM_*}\right) \sim \mathcal{N}(0, 5)$ and $p(c) \sim \mathcal{N}(-12, 5)$ respectively. We sample using four chains, each with 2000 warm-ups and 2000 sampling iterations. We report parameter estimates based on the mean and standard deviation of their posterior samples. We use the \hat{R} diagnostic of Vehtari et al. (2019) to assess the convergence of MC chains and only accept fits where $\hat{R} < 1.05$.

The joint posterior distribution for the slope and intercept of the overall SN rate versus stellar mass are shown in Fig. A1. The two parameters are highly degenerate, yet well constrained. This degeneracy manifests as the spread of potential linear fits as drawn in light green on Fig. 10.

Figure A1. Joint posterior distribution for the slope and intercept of the linear fit to the SN rate per galaxy per year as a function of stellar mass (Section 4; Fig. 10).

APPENDIX B: POSTERIOR DISTRIBUTIONS FOR DTD FITS

In this section we present the joint and marginal posterior distributions for the various fits of the DTD presented in Section 6. Posteriors have been displayed using v0.33.0 of ChainConsumer (Hinton 2016).

Figure B1. Posterior distributions for DTD slope β and normalization A for SNe Ia split by their x_1 parameter.

Figure B2. Posterior distributions for DTD slope β and normalization A for SNe Ia split by their c parameter.

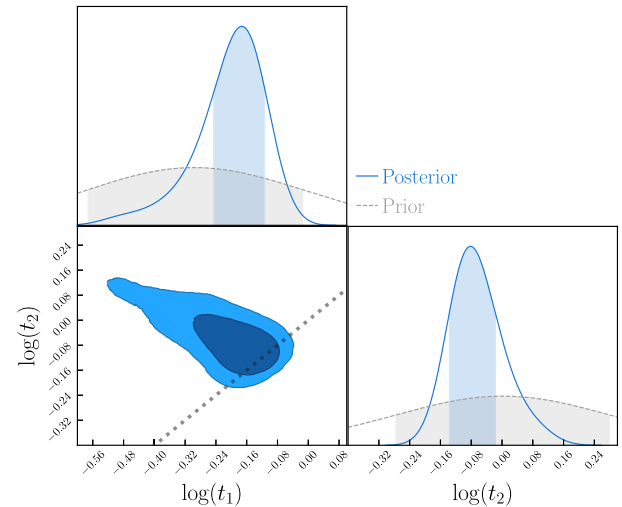

Figure B3. Posterior distributions for t_1 and t_2 of the model presented in Section 6.1.
