ABSTRACT

Hemodynamic forces represent an epigenetic factor during heart development and are supposed to influence the pathology of the grown heart. Cardiac blood motion is characterized by a vortical dynamics, and it is common belief that the cardiac vortex has a role in disease progressions or regression. Here we provide a preliminary demonstration about the relevance of maladaptive intra-cardiac vortex dynamics in the geometrical adaptation of the dysfunctional heart. We employed an in vivo model of patients who present a stable normal heart function in virtue of the cardiac resynchronization therapy (CRT, bi-ventricular pace-maker) and who are expected to develop left ventricle remodeling, if pace-maker was switched off. Intra-ventricular fluid dynamics is analyzed by echocardiography (Echo-PIV). Under normal conditions, the flow presents a longitudinal alignment of the intraventricular hemodynamic forces. When pacing is temporarily switched off, flow forces develop a misalignment hammering onto lateral walls, despite no other electro-mechanical change is noticed. Hemodynamic forces result to be the first event that evokes a physiological activity anticipating cardiac changes and could help in the prediction of longer term heart adaptations.
**INTRODUCTION**

Mechanical forces have an active biological role during morphogenesis. They stimulate cellular growth and multiplication at the microscopic level which eventually reflect on the macroscopic shaping of an organ as a whole (Farge, 2011; Freund et al., 2012). The importance of hemodynamic forces for heart morphogenesis was first demonstrated in the zebrafish, in which it was experimentally shown that intracardiac stresses imparted by the blood flow lead the proper heart development (Hove et al., 2003). Biological fluid forces are known to play a central role in the growth of the embryonic heart and vasculature (Reckova et al., 2003; Santhanakrishnan and Miller, 2011) so that the phenotype of congenital heart abnormalities was suggested to depend from the characteristics of blood flow forces acting on the developing tissues (Gruber and Epstein, 2004). Along the same line, it is suggested that hemodynamic forces should participate to pathological developments and therapeutic outcomes in the grown heart, although evidences are still lacking (Pasipoularides, 2012; Pedrizzetti et al., 2014).

The clinical syndrome of heart failure (HF) is the principal social threatening cardiac progressive dysfunction. It presents either as a primary pathology or because of a majority of primary diseases. The salient feature of HF is the development of left ventricle (LV) remodeling: a geometric modification and dilatation of the ventricular chamber that progressively reduce its muscular pumping ability. Despite modern treatments, hospitalization and death rate remain high, with nearly 50% people diagnosed with HF dying within 5 years (Levy et al., 2002).

The physiological causes that lead to LV remodeling are mainly ascribed to an increase of stresses on the myocardial fibres (around a scar area, because of higher systemic pressure etc.), which stimulate the growth and multiplication of cells and give rise to an increase of muscular thickness and then dilatation. Current models of cardiac remodeling, however, are not consistently predictive and remain rather primitive (Opie et al., 2006; Sengupta and Narula, 2008); although a variety of pathophysiologic
mechanisms have been suggested, there is paucity of methods capable of effectively forecasting the future risk of cardiac remodeling (Wu et al., 2008; Nijveldt et al., 2009). All existing models, in particular, do not account of the presence of hemodynamic forces that can trigger the sequence of events leading to progressive LV remodeling and eventually to HF (Pasipoularides, 2012; Pedrizzetti et al., 2014).

The distinguishing feature of cardiac blood flow is the presence of vortices. The sinuous flow paths around the vortex in the human heart were elegantly described by magnetic resonance visualization (Kilner et al., 2000). It was suggested that the asymmetric vortical arrangement was the flow functional counterpart of the looped heart structure that enhances the conservation of momentum from the entry jet to the ejected flow. It ensures an energetic balance of the longitudinal function during the filling-emptying mechanism with left ventricle asymmetry and vortex formation (Pedrizzetti and Domenichini, 2005). In recent years, numerous results about vortex dynamics in the human LV were produced using different techniques, from numerical simulations to magnetic resonance, to echocardiography (Markl et al., 2011; Sengupta et al., 2012). All these studies evidenced the presence of an intimate relationship between cardiac function and quality of intra-ventricular fluid dynamics.

A firm evidence of the relevance of LV fluid dynamics to the development and progression of a cardiac pathology, however, is still lacking. This is partly imputable to the difficulty of building comprehensive mathematical or experimental models capable of accounting of the complex transduction mechanism, where the large scale flow forces are sensed at the microscopic level, turn into cellular multiplication, and lead to alterations at the organ level (Pasipoularides, 2012). Here, we present an initial evidence that the quality of cardiac fluid mechanics could be a participating factor of heart adaptation mechanisms, namely adverse or reverse remodeling. These results may provide an interpretative ground for future clinical studies.
METHODS

We consider an *in vivo* model made of formerly HF patients with dilated LV that were subjected to cardiac resynchronization therapy (CRT, implant of bi-ventricular pace-maker) and that returned (after at least six months of therapy) to a stable condition with a LV of normal dimension and functional parameters. These subjects represent a special prototype model with a stably normal cardiac function with the support of the CRT. The same subjects, whether CRT is switched off, are expected to turn into an unstable state undergoing heart adaption and, within a few weeks, falling back into LV remodeling. The realization of both stable and unstable states on a same subject, at few seconds of distance, permits a deterministic one-to-one comparison.

These subjects were selected from a population of 30 (age 58±11 years old) who underwent CRT device implant according to the in use guidelines for a non-ischemic and non-valvular dilated cardiomyopathy. Exclusion criteria were atrial fibrillation, severe renal insufficiency, acute coronary syndrome, cardiac insufficiency of advanced grade (NYHA IV), severe either pulmonary hypertension or obstructive pulmonary disease, uncontrolled systemic hypertension. At follow-up, all patients were in sinus rhythm with spontaneous atrio-ventricular conduction. In this population we identified a sub-group of 6 patients who presented a high response to the therapy (super-responders). This sub-group was characterized by a pre-CRT dilated LV with large volumes (end-systolic volume>160 ml, end-diastolic volume>200 ml) and reduced ejection fraction (EF<30%). The high response to the therapy, was defined by a reduction of more than 40% in both LV volumes and an EF above 40%. In the same population, as counter-examples, we also identified 2 subjects presenting the opposite outcome and did not get any benefit from the CRT (non-responders) whose LV volumes were not significantly reduced (<10%) after six months of therapy. The selection of extreme sub-groups (super-responders and non-responders) was driven by the objective of developing a deterministic biomechanical interpretation at an individual level and avoiding the statistical analysis typical for clinical results that are not the scope...
of the present study. All subjects underwent echocardiographic examination. Cardiac mechanical contraction was evaluated by the global longitudinal strain (GLS) while its synchronicity was evaluated by the standard deviation of time to peak of transversal strain (SD-TTS) (Knappe et al., 2011) assessed in bi-plane recordings (2- and 4-chambers apical views). Intra-cardiac fluid dynamics was measured using an echographic adaptation of the optical particle image velocimetry, widely validated in clinical applications (Echo-PIV) (Sengupta et al., 2012), on a longitudinal plane containing both the inlet and outlet valves (3-chambers view). Echo-PIV permits a good temporal resolution but presents some limitations in the quality of spatial distribution (noise) and in the detection of high velocities (Kheradvar et al., 2010). For these reasons velocity information was here employed in averaged and normalized terms only, that are less affected by local and instantaneous inaccuracies.

The dynamic interchange between flow and tissue was summarized by the rate of fluid momentum

\[ \mathbf{m}(\mathbf{x}, t) = \rho \left( \frac{\partial \mathbf{v}}{\partial t} + \mathbf{v} \cdot \nabla \mathbf{v} \right) ; \]

(1)

where \( \rho = 1050 \text{ Kg/m}^3 \) is the blood density and \( \mathbf{v}(\mathbf{x}, t) \) is the 2D velocity vector field. The field \( \mathbf{m}(\mathbf{x}, t) \) corresponds, by Navier-Stokes balance, to the sum of the pressure gradient and the viscous terms, where the latter is mostly negligible with the exception of the region next to the walls.

A measure of the global hemodynamic force (per unit depth) exerted by the fluid on the surrounding tissue is obtained after spatial integration of (1)

\[ \mathbf{M}(t) = \iint_{LV} \mathbf{m} dA . \]

(2)

taken over the image area contained inside the LV chamber. Directional distribution of hemodynamic forces during the entire heart cycle is summarized in terms of an intensity-weighted polar histogram (like that used for wind description). For this, the circumference is divided in 12 sectors, centered in
θ_i=(2i-1)\pi/12, i=1..12, and the force moduli during all the time instants in the heartbeat are summed up when the angle falls in a corresponding sector. The resulting values are normalized to unit sum to provide an intensity-weighted angular frequency distribution.

**RESULTS AND DISCUSSION**

The intraventricular fluid dynamics under stable conditions (pace-maker ON), estimated from Echo-PIV (one example is shown in Figure 1), agrees with what was previously described in literature: a circulatory pattern forming during the LV filling (diastole) that accompanies blood from the inlet toward the outflow where it converges like in a funnel during the ejection (systole) (Kilner et al., 2000; Pedrizzetti and Domenichini, 2014; Markl et al., 2011; Sengupta et al., 2012). When the pace-maker therapy is discontinued (pace-maker OFF), the LV mechanical function should manifest early signs of mechanical dysfunction driving toward the spiral of events leading to remodeling and HF. However, the overall fluid dynamics does not evidence qualitative alterations. Some minor differences are shown, for example, in Figure 1 where the entering jet is slightly displaced toward the side wall, or the converging motion during ejection presents sharper bends. These small changes, however, globally reflect into large deviations of intraventricular momentum away from the normal, longitudinal base-apex alignment.

The directional deviation on intraventricular forces becomes evident in Figure 2, where the polar histogram of \( \mathbf{M}(t) \) during the entire heartbeat is reported for 4 subjects. In the stable configuration (pace-maker ON, left column in Figure 2) the momentum is well aligned along the base-apex LV axis, in compliance with the dynamics of the filling-emptying process. Few seconds after the pacing is switched off (right column), the LV enters into a physiologically unstable state whose dynamics anticipates heart adaptation. In this condition, flow loses its natural alignment, intraventricular forces
develops transversal components, despite cardiac contractility and synchrony parameters (GLS, SDTTS) do not evidence noticeable (or measurable) changes.

As a counter-example we performed the same analysis on the non-responders subjects. Differently from before, as summarized in Figure 3, in those subjects the flow was neither aligned when the peacemaker was active nor when it was switched off. Their state was unstable (or meta-stable, given the extreme deformation) and the therapy was not able to create longitudinal hemodynamic forces.

These observations suggest that a modification of the natural fluid dynamics pattern is the first recognizable mechanical phenomenon associated with an unstable condition that anticipates LV remodeling. Flow changes presumably are due to minor modifications in the synchrony of tissue motion, like local and short-lasting accelerations, that are difficult to detect directly but that reflect on the overall dynamic balance of the incompressible fluid contained in the LV chamber.

Hemodynamics forces, by themselves, are not able to provoke large stresses that may deform a tissue by fatigue. However, during morphogenesis, endothelial cells are able to sense vorticity and loading conditions via shear changes (mechano-sensing), transforming any abnormal condition into adaptive responses (mechano-transduction) (Pedrizzetti et al., 2014). The presence of forces acting on inappropriate regions at inappropriate timings presumably activates, through a plethora of intracellular signaling pathways, a physiological adaption mechanism that under prolonged over-stimulation leads to the development of LV adaptation.
CONCLUSION

These results provide initial evidence that the natural longitudinal alignment of hemodynamic forces is a necessary condition for the presence of a physiologically LV stable state and to avoid heart adaptation. By logical equivalence, the lack of flow alignment is a sufficient condition for physiologically instability inducing heart adaptation.

Hemodynamic forces are known to participate to heart morphogenesis during the development of the embryonic heart. This study suggests that they also participate to physiological adaptations in the grown heart. In a more general perspective, large scale flow phenomena influence, through the mediation of sensing and transduction at the cellular level, the long term shaping of the cardiac organ as a whole.

Epigenetic mechanisms are a concurring factor in heart pathological adaptation and they are mediated by mechanical forces. The deeper understanding of how physical phenomena are associated to physiological outcomes could open a new comprehension about expression of phenotypes not revealed by (and not written in) the genetic structure only.
