A model-independent search for a narrow resonance produced in proton–proton collisions at \( \sqrt{s} = 8 \) TeV and decaying to a pair of 125 GeV Higgs bosons that in turn each decays into a bottom quark–antiquark pair is performed by the CMS experiment at the LHC. The analyzed data correspond to an integrated luminosity of 17.9 fb \(^{-1}\). No evidence for a signal is observed. Upper limits at a 95% confidence level on the production cross section for such a resonance, in the mass range from 270 to 1100 GeV, are reported. Using these results, a radion with decay constant of 1 TeV and mass from 300 to 1100 GeV, and a Kaluza–Klein graviton with mass from 380 to 830 GeV are excluded at a 95% confidence level.

1. Introduction

Following the discovery of a Higgs boson (H) at the CERN LHC [1–3], with mass around 125 GeV and properties so far consistent with the standard model (SM) of particle physics, it has become important to search for new resonances that decay into pairs of such Higgs bosons. While non-resonant pair production of the Higgs boson is allowed in the SM, the theoretical production cross section is approximately 10 fb \([4]\) and well beyond the sensitivity of currently acquired data. However, several well-motivated hypotheses of physics beyond the standard model posit narrow-width resonances that decay into pairs of Higgs bosons, and could be produced with large enough cross sections to be probed with existing data. The radion [5] and Kaluza–Klein (KK) gravitons in the Randall–Sundrum (RS1) [6] model of warped extra dimensions are examples of such resonances [7].

This letter reports the results of a model-independent search for the resonant pair production of Higgs bosons. The search for the narrow width resonance, denoted by \( X \), is performed in the 270–1100 GeV mass range. Data from proton–proton collisions at the LHC and recorded by the CMS experiment corresponding to an integrated luminosity of \( 17.9 \pm 0.5 \) fb \(^{-1}\) at \( \sqrt{s} = 8 \) TeV is used. We perform this search for the case where both Higgs bosons decay into bottom quark–antiquark pairs (bb) \([8]\). The main challenge of this search is to distinguish the signal of four bottom quarks in the final state that hadronize into jets (b jets) from the copious multijet background described by quantum chromodynamics (QCD) in pp collisions. We address this challenge by suitable event selection criteria that include dedicated b-jet identification techniques and a model of the multijet background that is validated in data control regions. Our results may be compared with a search performed by the ATLAS experiment \([9]\) that also probes the physics of resonant Higgs boson pair production, albeit in the channel where one Higgs boson decays to bottom quarks and the other decays to photons.

2. Detector and event reconstruction

A detailed description of the CMS detector, together with a description of the coordinate system used and the relevant kinematic variables, can be found in Ref. \([10]\). The central feature of the CMS apparatus is a superconducting solenoid of 6 m internal diameter that generates an axial magnetic field of 3.8 T. Within the solenoid volume are a silicon pixel and strip tracker, a lead tungstate crystal electromagnetic calorimeter, and a brass and scintillator hadron calorimeter. Muons are detected and their properties measured in...
gas-ionization detectors embedded in a steel flux-return yoke outside the solenoid. Jets are reconstructed using the anti-$k_t$ clustering algorithm \cite{11,12} with a distance parameter of 0.5 applied on the collection of particle candidates reconstructed by the particle-flow (PF) algorithm \cite{13,14}. The PF algorithm reconstructs and identifies each individual particle with a combination of information from the various elements of the CMS detector. To mitigate the effect of additional particles that do not originate from the hard interaction in jet reconstruction, we subtract charged hadrons that do not arise from the primary vertex associated with the jet from the collection of clustered particles. Further, an average neutral energy density from particles not arising from the primary vertex is evaluated and subtracted from the jets \cite{15}. Energy corrections for the jets are determined as functions of the jet transverse momentum $p_T$ and pseudorapidity $\eta$. Jet identification criteria \cite{16} to reject detector noise misidentified as jets, and jets not originating from the hard interaction are also applied.

In order to identify (tag) b jets, we rely on the fact that bottom quarks hadronize into b hadrons which have decay lengths of the order of $\tau = 450 \mu$m. Thus, their decay products originate from secondary vertices, while tracks of jets that have impact parameters with respect to the primary vertex of a similar scale. The pixel tracker provides an impact parameter resolution of about 15 $\mu$m for charged tracks with $|\eta| < 2.4$. To maximize the b-tagging performance of the detector, we combine the output discriminants of several b-tagging algorithms described in Ref. \cite{17} with a trained artificial neural network. This we call the combined multivariate (CMVA) algorithm. In particular, we combine the outputs of the combined secondary vertex (CSV) tagger that uses secondary vertices identified by the inclusive vertex finder (IVF) algorithm \cite{18}, the jet probability (JP) tagger, and the two soft lepton taggers.

The first level of the trigger, consisting of customized processors, collects data for this analysis using information from the calorimeters and requires two jets to exceed $p_T$ thresholds of 56 or 64 GeV, depending on luminosity conditions. The second level of the trigger, consisting of software algorithms executed on a farm of commercial processors, uses information from the entire detector to reconstruct PF jets, and requires four PF jets with $|\eta| < 2.4$ and $p_T > 30$ GeV, of which two jets must have $p_T > 80$ GeV. Further, to record signal events and reject background QCD multijet events, two jets are required to be tagged by the CSV b-tagging algorithm implemented at the trigger.

3. Simulated samples

To model the production of a generic narrow-width spin-0 resonance, we use a Monte Carlo simulation of the RS1 radion produced through gluon fusion. The angular distributions of a spin-2 resonance are distinct from those of a spin-0 resonance, and result in different kinematic distributions. Therefore, we evaluate the signal efficiencies for a narrow-width spin-2 resonance from a separate simulation of the first excitation of the KK graviton produced through gluon fusion in the same extra dimension scenario as the radion. The resonance is forced to decay to a pair of Higgs bosons where both Higgs bosons decay to b$\bar{b}$. Samples of these signal events, as well as background events from diboson, W + jets, Z + jets and top-quark pair production (t\bar{t}) processes, are generated using the MadGraph 5.1 \cite{19} program interfaced with the PYTHIA 6.4 \cite{20} for parton showering and hadronization. QCD multijet event samples are simulated with the PYTHIA 6.4 program. A sample of events where the Higgs boson is produced in association with a Z boson is simulated using the POWHEG event generator \cite{21,22,23} interfaced with the HERWIG++ \cite{24} program for showering and hadronization. We set the PYTHIA 6.4 parameters for the underlying event to the ZZ* tune \cite{25}. The response of the CMS detector is modeled using GEANT4 \cite{26}.

On average, 21 pp interactions occurred per bunch crossing in the data used in this analysis. Additional simulated pp interactions overlapping with the event of interest were added to the simulated samples to reproduce the distribution of the number of primary vertices per event reconstructed in data.

4. Event selection

The trigger-level jet $p_T$ thresholds confine our search for a narrow-width $X \rightarrow HH \rightarrow b\bar{b}b\bar{b}$ resonance to masses above 270 GeV. Beyond $m_{X} \approx 800$ GeV, the selection efficiency is increasingly limited by the merging of jets from the same Higgs boson, and we curtail this search at 1100 GeV. The kinematic distributions of the decay products vary substantially over this mass range. Therefore, to optimize the search sensitivity, we use different event selection criteria in three main kinematic regions: the low-mass region (LMR) for mass hypotheses from 270 to 450 GeV, the medium-mass region (MMR) for masses from 450 to 730 GeV, and the high-mass region (HMR) for masses from 730 to 1100 GeV.

Event selection begins with the identification of events containing at least four jets in the central region of the detector ($|\eta| < 2.4$) that are b-tagged and have $p_T > 40$ GeV. To b-tag a jet, we require it to pass a working point for the CMVA algorithm that maximizes the sensitivity of this search. For jets with $p_T > 40$ GeV and $|\eta| < 2.4$ this working point yields a 75% efficiency for tagging jets originating from b hadrons and a mistagging rate of 3% for light-flavor jets. For the LMR, we combine these b jets into pairs to create HH candidates such that $m_{b\bar{b}} - 125$ GeV < 35 GeV for each candidate Higgs boson. The mass resolution on the Higgs boson in the LMR is found to be approximately 9 GeV. Selected HH candidates are required to have at least two jets with $p_T > 90$ GeV. In the MMR, signal events have large Lorentz factors for the Higgs boson candidates. Therefore, HH candidates for this region are constructed from four jets such that the $\Delta R = \sqrt{\Delta \eta^2 + \Delta \phi^2}$ between the jets associated with an H candidate remain within 1.5, where $\Delta \eta$ and $\Delta \phi$ are the differences in the pseudorapidities and azimuthal angles of the two jets. For the HMR, we use the same criteria used in the MMR with an additional requirement of $p_T > 300$ GeV on one of the H candidates to better discriminate signal events from background. In all three regions, in case of multiple HH candidates in an event, we plot their masses, $m_{H_1}$ and $m_{H_2}$, on a two-dimensional histogram as shown in Fig. 1. $H_1$ and $H_2$ are chosen at random from the two reconstructed H candidates. As the final selection criterion applied in each of the three mass hypothesis regions, we require events to fall within the signal region (SR) defined as

$$\sqrt{\Delta m^2_{H_1} + \Delta m^2_{H_2}} < 17.5 \text{ GeV},$$

where $\Delta m_{H_{1,2}} = m_{H_{1,2}} - 125$ GeV.

The efficiencies of these selection criteria for spin-0 and spin-2 resonances at representative masses are shown in Table 1. The major loss in efficiency for all mass hypotheses comes from the b-tagging requirement for 4 jets. For the 300 GeV mass hypothesis, this is compounded by the trigger inefficiency. The distribution of the aforementioned $\Delta R$ between jets from a single Higgs boson is narrower for the spin-2 resonance, and thus requiring $\Delta R < 1.5$ results in a higher efficiency for it.

5. Signal modeling

For signal events, the aforementioned event selection criteria are expected to produce a sharp peak in the $m_X$ distribution over a relatively featureless background from events arising from SM
processes. The interference between SM background processes and the narrow resonant signal is expected to be negligible. To search for signal events at various mass hypotheses, we fit the \( m_X \) distribution in data events in the SR to a parametric model for the signal peak on top of parametric models appropriate for components of the SM background. This procedure is performed for the LMR, the MMR, and the HMR separately.

To improve the mass resolution of the signal \( X \to HH \) resonance, we perform a fit that constrains the invariant masses of the Higgs boson candidates. In the fit, the momenta of the reconstructed \( b \) jets are allowed to float within their expected resolutions. Since the uncertainty in the reconstructed mass of the Higgs boson candidate due to the measurement of jet direction is smaller than that due to the measurement of jet energy, this constraint mainly affects the latter. This fit improves the invariant mass resolution of the reconstructed signal resonance by 20–40%, depending on the mass hypothesis. Extensive tests in background-dominated control regions in data show that no artificial structures are introduced in the background mass distributions by this procedure.

We build the parametric model for each signal mass hypothesis by fitting the shape of the \( m_X \) distribution of simulated events that are accepted by the selection criteria and corrected for differences between data and simulation. A sum of two Gaussian functions, requiring five parameters, is used for the LMR fit to account for tails in the distribution from incorrect combinations of jets. In the MMR and the HMR, we fit a function with a Gaussian core smoothly extended on both sides to exponential tails, such that the function is continuous both in its value and its first derivative. This requires two parameters for the mean and width of the Gaussian function, and two other parameters for the exponential tails on both sides.

An example of a parametric model for the MMR signal obtained through this procedure is shown in Fig. 2. While the model is constructed for the mass hypothesis of 700 GeV, its Gaussian core peaks at 714 GeV and has a width of 21 GeV. This mass shift is found to be linear in \( m_X \) and occurs due to the aforementioned constraint of jet momenta to \( \mu_H \).

### 6. Background modeling

While the composition of background events in the SR is expected to be dominated by QCD multijet processes, we find through simulation that \( t\bar{t} \) production contributes approximately 22%, 27%, and 24% in the LMR, MMR, and HMR, respectively. We also find that \( Z+\)jets, \( ZZ \), and \( 2H \) processes contribute less than 1% of the background and therefore neglect them in this analysis. The \( m_X \) distribution of these \( t\bar{t} \) events is found to be somewhat different in shape from that of QCD multijet events, and therefore we treat it as a distinct component of the background and model it with a parametric form. We obtain this parametric form by fitting the shape of the \( m_X \) distribution of simulated \( t\bar{t} \) events accepted by the event selection criteria to a function with a Gaussian core smoothly extended to an exponential tail on the high side. This function, henceforth referred to as GaussExp, is continuous in its value and its first derivative. It has two parameters for the mean and width of the Gaussian function and one parameter for the decay constant of the exponential tail. This model is normalized to a \( t\bar{t} \) cross section of 234 pb [27], and is allowed to float with a systematic uncertainty of 15% in the final fit to account for theoretical and measurement uncertainties in our kinematically boosted region.

We use the GaussExp parametric model to fit the \( m_X \) distribution of the QCD multijet component of the background in the SR. With the SR kept blinded, we motivate and validate this choice of parametric model by the fact that it fits well the shape of the \( m_X \) QCD multijet background distributions in several different regions of the \((m_{H_1}, m_{H_2})\) plane depicted in Fig. 1 and described below.
Fig. 3. The \( m_X \) distributions in data (after the \( t\bar{t} \) background has been subtracted) in the SB of the MMR (top left), the CR of the MMR (top right), the VS of the LMR (bottom left), and the VR of the LMR (bottom right). The distributions are fitted to the GaussExp parametric model. The shaded regions correspond to \( \pm 1 \sigma \) variations of this fit. Here \( n \) is the number of degrees of freedom in each fit. The pull, for a given bin, is defined as the number of data events minus the value of the fit model, divided by the uncertainty in the number of data events.

We do not aim to predict the parameters of the model in the SR from the other regions. These fits are performed for the LMR between 260 and 650 GeV, for the MMR between 400 and 900 GeV, and for the HMR between 600 and 1200 GeV. In each case the \( t\bar{t} \) contribution, as expected from simulation, is subtracted.

We define a sideband region (SB) to the SR as 17.5 GeV < \( \sqrt{\Delta m_{H_1}^2 + \Delta m_{H_2}^2} \) < 35 GeV and \( \Delta m_{H_1} \Delta m_{H_2} < 0 \). For events in this region, the \( m_X \) distribution is expected to be kinematically similar to that for events in the SR, since in each of the sidebands one of the reconstructed Higgs boson masses is slightly higher in value than for events in the SR while the other is slightly lower. As an example, Fig. 3 top left shows the fit performed for events in the SB passing the HMR selection. Another set of events that pass the kinematic requirements of the event selection criteria in the SR region of the \((m_{H_1}, m_{H_2}) \) plane but required to have one of the four jets not be b-tagged is selected to further test the applicability of the GaussExp model in describing the \( m_X \) distribution of the QCD multijet background in a different but kinematically similar region.
Fig. 4. The $m_X$ distribution in data in the SR between 260 and 650 GeV of the LMR (top left), between 400 and 900 GeV of the MMR (top right), and between 600 and 1200 GeV in the HMR (bottom). All distributions are fitted to the background-only hypothesis for illustration, showing the relative contributions of the QCD multijet (dashed–dotted red) and tt (dashed green) processes. The pull, for a given bin, is defined as the number of data events minus the value of the background-only fit, divided by the uncertainty in the number of data events. Also for illustration, we overlay the signal models of the spin-0 resonance (dotted blue) corresponding to mass hypotheses and production cross sections of 350 GeV and 653 fb for the LMR, 700 GeV and 176 fb for the MMR, and 900 GeV and 8.1 fb for the HMR. These cross sections correspond to the observed upper limits, which are computed for signal mass hypotheses from 270 to 450 GeV in the LMR, from 450 to 730 GeV in the MMR, and from 730 to 1100 GeV in the HMR. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)
This is called the data Control Region (CR), and the fit for these events, that would have otherwise passed the HMR selection, is also shown in Fig. 3 on the top-right. In both cases, the goodness of the fit, characterized by the $\chi^2$ per degree of freedom, is found to be reasonable.

These two cases already lend significant confidence to the choice of the GaussExp parametric model for the SR. However, we carry out further checks in neighboring validation regions (VR) with a corresponding sideband (VS) that are defined similarly to the SR and SB regions but with $m_{H_1} = m_{H_2}$ centered at different values. The good fits for the $m_X$ distributions in these regions not only demonstrate the applicability of the GaussExp model to describe these kinematically distinct QCD multijet events, but also that events in the VR are in fact kinematically similar to those in the VS. As examples, Fig. 3 bottom-left and bottom-right plots show the results of these fits for the LMR selection for the VS and the VR, respectively, both centered at $m_{H_1} = m_{H_2} = 90$ GeV. We obtain similar results for the VR centered at $m_{H_1} = m_{H_2} = 107.5, 142.5$ and 160 GeV.

While the GaussExp function fits well the $m_X$ distribution from QCD multijet events in all these distinct regions and therefore can be expected to be a good approximation of the parametric form of the true parent distribution for events in the SR, other similar parametric models could be chosen instead. Therefore, a systematic uncertainty associated with the choice of this parametric model is evaluated by assuming a 7th order Bernstein polynomial, which also fits the $m_X$ distribution well in the SB, to be the true distribution. Pseudo-datasets are generated from this polynomial function and fitted with the GaussExp function as well as other polynomial functions to compute biases in the reconstructed signal strength. This procedure is performed for each mass hypothesis. These biases are found to be of the order of 100 fb for the LMR, 10 fb for the MMR, and 20 fb for the HMR. We account for this bias as a signal-shaped systematic uncertainty in the background model with normalization centered at zero and a Gaussian uncertainty with standard deviation equal to the bias.

### 7. Systematic uncertainties

Sources of systematic uncertainties that affect the selection efficiencies for signal and t$\bar{t}$ events are listed in Table 2 and described below. We vary the jet energy scale [28] by its uncertainty as a function of jet $p_T$ and $n_T$ and find that this affects signal efficiencies by a relative factor of up to 0.2% and t$\bar{t}$ efficiencies by up to 0.8%. We evaluate the effect of uncertainty in the jet energy resolution by varying the jet energies according to the measured uncertainty. This is found to affect signal efficiencies by 2–7%, and t$\bar{t}$ efficiencies by 2–3%. These uncertainties affect not only the normalizations but also the parameters of the signal and t$\bar{t}$ models, and are taken into account as nuisance parameters in the final fit.

The trigger efficiencies for signal and t$\bar{t}$ events are evaluated approximately by passing generated events through a trigger simulation. We then correct these efficiencies for differences between simulation and data by computing the difference in a t$\bar{t}$-enriched control region obtained using a trigger that requires at least one muon with $p_T > 24$ GeV. Further, event selection criteria requiring at least one muon with $p_T > 40$ GeV and at least four jets in the central region of the detector with $p_T > 40$ GeV are applied. The data-to-simulation correction factor is characterized by the $p_T$ and CMVA discriminants of the relevant jets. Uncertainties in this factor impact signal efficiencies by 6–18%, and t$\bar{t}$ efficiencies by 7–9%.

The b-tagging efficiencies of the CMVA algorithm for signal and t$\bar{t}$ events are also evaluated approximately through simulation and then corrected by a data-to-simulation comparison. The comparison is performed in the same t$\bar{t}$-enriched control region as the calculation of the trigger efficiency. The correction factor for the b-tagging efficiencies is consistent with unity. The uncertainty in this factor for four b jets is evaluated to be 12.7%.

Additionally, the yields of signal events for a given production cross section and t$\bar{t}$ events are both affected by a 2.6% uncertainty in the measurement of the integrated luminosity [29].

### 8. Results

The $m_X$ distribution that we observe in data within the SR, along with a binned maximum-likelihood fit with the aforementioned parametric background models, are shown in Fig. 4. We compute the observed and expected upper limits on the cross section for pp → $X$ → $HH$ → bbbt at a 95% confidence level (CL) using the modified frequentist CL$_S$ method [30,31] by fitting the data with the parametric signal, t$\bar{t}$, and QCD multijet models. This is done separately in the disjoint ranges of $m_X$ for the individual regions described in Section 4, and the limits are presented together in Fig. 5. These limits are shown for the spin-0 resonance in the top plot, and the spin-2 resonance in the bottom plot. The green (dark) and yellow (light) bands respectively represent the 1σ and 2σ confidence intervals around the expected limits. The observed upper limits lie within 2σ of the expected upper limits, and thus we conclude that there is no significant deviation from the background-only hypothesis.

The theoretical cross section for the production via gluon fusion of a radion that decays to a pair of Higgs bosons [32] that each in turn decays to a b$\bar{b}$ pair with a branching fraction of 58% [33] is calculated using MadGraph 5.1 [34] and superimposed on the experimental cross section limit for the spin-0 resonance in the plot on the left. In this calculation, the correction factor used to account for next-to-leading-order effects for electroweak couplings [35] and next-to-next-to-leading-order effects for QCD couplings [36] is identical to that used for Higgs boson production through gluon fusion. The warped extra dimension scenario for this radion has the product of the curvature, $k$, and half the circumference of the extra dimension, $L$, set to 35, a radion decay constant of $\Delta R = 1$ TeV, and no radion-Higgs boson mixing. The theoretical cross section for the radion has an uncertainty of approximately 15% that is not used to compute the experimental limits on spin-0 resonance production shown in Fig. 5. Masses for the radion between 300 and 1100 GeV are excluded at a 95% CL. A similarly calculated theoretical cross section for the KK graviton as the resonance $X$, in the same warped extra dimension scenario, is overlaid on the limit for the spin-2 resonance in the plot at the bottom. Masses for such a graviton are excluded at a 95% CL between 380 and 830 GeV.
9. Summary

We have presented a model-independent search by the CMS experiment at the LHC for a narrow resonance produced in proton-proton collisions at $\sqrt{s} = 8$ TeV and decaying to a pair of 125 GeV Higgs bosons that in turn each decays into a bottom quark–antiquark pair. The analyzed data correspond to an integrated luminosity of 17.9 fb$^{-1}$. No evidence for a signal is observed. Upper limits at a 95% CL on the production cross section for such spin-0 and spin-2 resonances, in the mass range from 270 to 1100 GeV, are reported. Using these results, a radion with decay constant of 1 TeV and mass from 300 to 1100 GeV, and a Kaluza–Klein graviton with mass from 380 to 830 GeV are excluded at a 95% confidence level.

Acknowledgements

We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC and thank the technical and administrative staffs at CERN and at other CMS institutes for their contributions to the success of the CMS effort. In addition, we gratefully acknowledge the computing centers and personnel of the Worldwide LHC Computing Grid for delivering so effectively the computing infrastructure essential to our analyses. Finally, we acknowledge the enduring support for the construction and operation of the LHC and the CMS detector provided by the following funding agencies: BMWFW and FWF (Austria); FNRS and FWO (Belgium); CNPq, CAPES, FAPERJ, and FAPESP (Brazil); MES (Bulgaria); CERN; CAS, MoST, and NSFC (China); COLCIENCIAS (Colombia); MSES and CSF (Croatia); RPF (Cyprus); MoER, ERC IUT and ERDF (Estonia); Academy of Finland, MEC, and HIP (Finland); CEA and CNRS/IN2P3 (France); BMBF, DFG, and HGF (Germany); GSRT (Greece); OTKA and NIH (Hungary); DAE and DST (India); IPM (Iran); SFI (Ireland); INFN (Italy); MES and NRF (Republic of Korea); LAS (Lithuania); MOE and UM (Malaysia); CINVESTAV, CONACYT, SEP, and UASLP-FAI (Mexico); MBIE (New Zealand); PAEC (Pakistan); MSHE and NSC (Poland); FCT (Portugal); JINR (Dubna); MON, RosAtom, RAS and RFBR (Russia); MESTD (Serbia); SEIDI and CPAN (Spain); Swiss Funding Agencies (Switzerland); MST (Taipei); ThEPCenter, IPST, STAR and NSTDA (Thailand); TUBITAK and TAEK (Turkey); NASU and SIF (Ukraine); STFC (United Kingdom); DOE and NSF (USA).
