Performance of missing transverse momentum reconstruction in proton-proton collisions at $\sqrt{s} = 13$ TeV using the CMS detector

The CMS collaboration

E-mail: cms-publication-committee-chair@cern.ch

ABSTRACT: The performance of missing transverse momentum ($p_T^{\text{miss}}$) reconstruction algorithms for the CMS experiment is presented, using proton-proton collisions at a center-of-mass energy of 13 TeV, collected at the CERN LHC in 2016. The data sample corresponds to an integrated luminosity of 35.9 fb$^{-1}$. The results include measurements of the scale and resolution of $p_T^{\text{miss}}$, and detailed studies of events identified with anomalous $p_T^{\text{miss}}$. The performance is presented of a $p_T^{\text{miss}}$ reconstruction algorithm that mitigates the effects of multiple proton-proton interactions, using the “pileup per particle identification” method. The performance is shown of an algorithm used to estimate the compatibility of the reconstructed $p_T^{\text{miss}}$ with the hypothesis that it originates from resolution effects.

1 Introduction

Weakly interacting neutral particles produced in proton-proton (pp) collisions at the LHC traverse the collider detectors unobserved. However, when such particles are produced along with strong or electromagnetically interacting particles, their presence can be inferred through the measured momentum imbalance in the plane perpendicular to the beam direction, which is referred to as the missing transverse momentum ($p_T^{\text{miss}}$), and its magnitude is $p_T^{\text{miss}}$.

The precise determination of $p_T^{\text{miss}}$ is critical for standard model (SM) measurements that use final states with neutrinos, such as those containing leptonic decays of the W boson. In addition, $p_T^{\text{miss}}$ is one of the most important observables in searches for physics beyond the SM that target new weakly interacting particles. The $p_T^{\text{miss}}$ stemming from weakly interacting particles will be collectively referred to as “genuine $p_T^{\text{miss}}$” in what follows. However, $p_T^{\text{miss}}$ reconstruction is sensitive to the experimental resolutions, to mismeasurements of reconstructed particles, and to detector artifacts. The performance of $p_T^{\text{miss}}$ is also affected by additional pp interactions in the same or nearby bunch crossings (pileup). A detailed understanding of all these effects, both in real and simulated data, is important to achieve optimal $p_T^{\text{miss}}$ performance.

In this paper, we present studies of $p_T^{\text{miss}}$ reconstruction algorithms using Monte Carlo simulation, and data collected in 2016 with the CMS detector [1] at the LHC [2], corresponding to an integrated luminosity of $35.9\,\text{fb}^{-1}$, and are applicable to the 2015–2018 data-taking period (LHC Run 2). A brief overview of the CMS detector is given in section 2. Information about event reconstruction is discussed in section 3, and a description of the different $p_T^{\text{miss}}$ reconstruction algorithms is provided in section 4. Information about event simulation and selection is provided in sections 5 and 6. In section 7, sources of anomalous $p_T^{\text{miss}}$ measurements from detector and reconstruction artifacts, and methods for identifying and mitigating them, are described. The performance of the $p_T^{\text{miss}}$ reconstruction at the trigger level is discussed in section 8. Section 9 details the performance of the $p_T^{\text{miss}}$ algorithms in events with and without genuine $p_T^{\text{miss}}$. The algorithm that provides an estimate of the $p_T^{\text{miss}}$ significance is described in section 10. A summary is given in section 11.

2 The CMS detector

The central feature of the CMS apparatus is a superconducting solenoid of 6 m internal diameter, providing a magnetic field of 3.8 T. Within the solenoid volume are a silicon pixel and strip tracker, a lead tungstate crystal electromagnetic calorimeter (ECAL), and a brass and scintillator hadron calorimeter (HCAL), each composed of a barrel and two endcap sections. The pseudorapidity ($\eta$) coverage of the ECAL (HCAL) barrel is $|\eta| < 1.479$ ($|\eta| < 1.3$) and endcap is $1.479 < |\eta| < 3.0$ ($1.3 < |\eta| < 3.0$) respectively. Forward hadronic calorimeter (HF) extend the $\eta$ coverage up to $|\eta| < 5.2$.

In the ECAL and HCAL barrel region, the HCAL cells have widths of 0.087 in $\eta$ and 0.087 radians in azimuth ($\phi$). In the $\eta$-$\phi$ plane, and for $|\eta| < 1.479$, the HCAL cells map on to $5 \times 5$ ECAL crystal arrays (supercrystals) to form calorimeter towers projecting radially outwards from close to the nominal interaction point. In the ECAL and HCAL endcap regions, the coverage of the towers increases progressively to a maximum of 0.174 in $\Delta\eta$ and $\Delta\phi$. Within each tower, the energy deposits in ECAL and HCAL cells are summed to define the calorimeter tower energies [1], subsequently used to provide the energies and directions of hadronic jets.
The silicon tracker measures charged particles within the range $|\eta| < 2.5$ (tracker acceptance). It consists of 1440 silicon pixel and 15 148 silicon strip detector modules. Tracks with transverse momentum $p_T$ of $\approx 100$ GeV emitted within $|\eta| < 1.4$ have $p_T$ and impact parameter resolutions of 2.8% and 10 (20) $\mu$m in the transverse (longitudinal) direction [3].

Muons are measured in the range $|\eta| < 2.4$, with detection planes made using three technologies: drift tubes in the barrel, cathode strip chambers (CSC) in the endcaps, and resistive plate chambers both in the barrel and in the endcaps embedded in the iron flux-return yoke outside the solenoid [4].

Events of interest are selected using a two-tiered trigger system [5]. The first level (L1), composed of custom hardware processors, uses information from the calorimeters and muon detectors to select events at a rate of around 100 kHz. The second level, known as the high-level trigger (HLT), consists of a farm of processors running a version of the full event reconstruction software optimized for fast processing, and reduces the event rate to an average of 1 kHz before data storage.

A more detailed description of the CMS detector, together with a definition of the coordinate system used and the relevant kinematic variables, can be found in ref. [1].

### 3 Event reconstruction

The CMS particle-flow (PF) algorithm [6] aims to reconstruct and identify each individual particle with an optimized combination of information from the various components of the detector. Particles are identified as a mutually exclusive list of PF candidates: charged or neutral hadrons, photons, electrons, or muons. The PF candidates are then used to build higher-level objects, such as jets and $p_T^{\text{miss}}$.

Events are required to have at least one reconstructed vertex. When multiple vertices are reconstructed due to pileup, the vertex with the largest value of summed physics-object $p_T^2$ is the primary pp interaction vertex (PV).

Photon candidates are reconstructed from energy deposits in the ECAL using algorithms that check the compatibility of the clusters to the size and shape expected from a photon [7]. The identification of the candidates is based on shower-shape and isolation variables [8]. For a photon to be considered isolated, the scalar $p_T$ sum of PF candidates originating from the PV, within a cone of $\Delta R \equiv \sqrt{(\Delta \eta)^2 + (\Delta \phi)^2} < 0.3$ around the photon candidate, is required to be smaller than a given threshold. Only PF candidates that do not overlap with the electromagnetic shower of the candidate photon are included in the isolation sums. The exclusion of PF candidates associated with the photon in the isolation sum, also known as “footprint removal”, is significantly improved for the LHC Run 2.

The analyses described in this paper use two sets of photon identification criteria: “loose” and “tight”. The loose photon candidates are required to be reconstructed within $|\eta| < 2.5$, whereas tight photon candidates are required to be reconstructed in the ECAL barrel ($|\eta| < 1.44$). Tight photon candidates, used in the performance measurements discussed in section 9, are also required to pass identification and isolation criteria that ensure an efficiency of 80% for the selection of prompt photons and a sample purity of 95%. In the barrel section of the ECAL, an energy resolution of about 1% is achieved for unconverted or late-converting photons in the tens of GeV energy range. The remaining barrel photons have a resolution of about 1.3% up to $|\eta| = 1$, rising to about 2.5% at
$|\eta| = 1.4$. In the endcaps, the resolution of unconverted or late-converting photons is about 2.5%, whereas the remaining endcap photons have a resolution between 3 and 4% [7].

Electrons within the geometrical acceptance $|\eta| < 2.5$ are reconstructed by associating tracks reconstructed in the silicon detector with clusters of energy in the ECAL. Electron candidates are required to satisfy identification criteria [8] based on the shower shape of the energy deposit in the ECAL and the consistency of the electron track with the PV. Electron candidates that are identified as coming from photon conversions in the detector material are removed. The isolation requirement is based on the energy sum of the PF candidates originating from the PV within a cone of $\Delta R < 0.3$ around the electron direction, excluding PF candidates associated to the electron or identified as muons. The mean energy deposited in the isolation cone of the electron from pileup is estimated following the method described in ref. [8] and is subtracted from the isolation sum. Two types of electron identification selection requirements are also used: “loose” and “tight”. The loose electrons are selected with an average efficiency of 95% and up to 5% misidentification rate. The loose identification requirements are used in some of the analyses presented in this paper as part of selection requirements designed to remove backgrounds containing electrons, e.g. $Z \rightarrow e^+e^-$ events.

The tight electrons are selected with an average efficiency of 70% and an average misidentification rate of 1%, and are used to select events used in the performance measurements (section 9).

Muons within the geometrical acceptance $|\eta| < 2.4$ are reconstructed by combining information from the silicon tracker and the muon system [4]. They are required to pass a set of quality criteria based on the number of spatial points measured in the tracker and in the muon system, the fit quality of the muon track and its consistency with the PV. The isolation requirements for muons are based on the energy sum of the PF candidates originating from the PV within a cone of $\Delta R < 0.3$ around the muon direction, excluding PF candidates identified as electrons or muons. The muon isolation variable is corrected for pileup effects from neutral particles by subtracting half of the $p_T$ sum of the charged particles that are inside the isolation cone and not associated with the PV. Two types of muon identification selection requirements are used: “tight” and “loose”. The tight muons are selected with an average efficiency of 95% and are used to select the events analyzed in the performance measurement (sections 9 and 10), whereas the loose muons are selected with an average efficiency of 98% and are used when appropriate to veto background events with additional muons. The $p_T$ resolution for muons with $20 < p_T < 100$ GeV is 1% in the barrel and better than 3% in the endcaps. The $p_T$ resolution in the barrel is better than 10% for muons with $p_T$ up to 1 TeV [4].

Hadronically decaying $\tau$ lepton candidates detected within $|\eta| < 2.3$ are required to pass identification criteria using the hadron-plus-strips algorithm [9]. The algorithm identifies a jet as a hadronically decaying $\tau$ lepton candidate if a subset of the particles assigned to the jet is consistent with the decay products of a $\tau$ candidate. In addition, $\tau$ candidates are required to be isolated from the surrounding activity in the event. The isolation requirement is computed by summing the $p_T$ of the PF charged and PF photon candidates within an isolation cone of $\Delta R = 0.5$, around the $\tau$ candidate direction. A more detailed description of the isolation requirement can be found in ref. [9].

Jets are reconstructed by clustering PF candidates using the infrared- and collinear-safe anti-$k_T$ algorithm [10] with a distance parameter of 0.4. To reduce the effect of pileup collisions, charged PF candidates that originate from pileup vertices are removed [11] before the jet clustering. The jet momentum is determined as the vector sum of all particle momenta in the jet, and is found from simulation to be within 5 to 10% of the true momentum over the full $p_T$ spectrum and detector
acceptance. An energy correction is applied to jet energies to subtract the contribution from pileup. Jet energy corrections, are derived from simulation to adjust the measured jets based on a ratio of the average measured jets to the simulated average jets. Measurements done in situ of the momentum balance in dijet, quantum chromodynamics (QCD) multijet, γ+jet, and leptonic Z+jet events are used to correct for any residual differences in jet energy scale (JES) in data and simulation [11].

Jets originating from the hadronization of bottom (b) quarks are identified (“tagged”) via a combined secondary vertex algorithm [12]. The working point of this algorithm provides an average efficiency of ~ 80% for the identification of jets originating from b quarks whereas the misidentification rate for light quarks or gluons is ~ 10%, and ~ 40% for charm quarks.

4 Reconstruction and calibration of $p_T^{\text{miss}}$

At hadron colliders, the reconstructed $p_T^{\text{miss}}$ is a useful quantity because the net momentum in the plane transverse to the beam is known to be nearly zero from the initial conditions. Therefore, the total $p_T$ of weakly interacting final-state particles can be inferred from the negative vector $\vec{p}_T$ sum of all visible final-state particles. CMS event reconstruction employs two distinct $p_T^{\text{miss}}$ reconstruction algorithms, described in the following, both based on PF candidates.

4.1 The $p_T^{\text{miss}}$ reconstruction algorithms

The first $p_T^{\text{miss}}$ reconstruction algorithm, referred to as PF $p_T^{\text{miss}}$ in this paper, defines $\vec{p}_T^{\text{miss}}$ as the negative vector $p_T$ sum of all the PF candidates in the event [13, 14]. The PF $p_T^{\text{miss}}$ is used in the majority of CMS analyses, since it provides a simple, robust, yet very performant estimate of the $p_T^{\text{miss}}$ reconstruction. A second algorithm has been developed to further reduce the dependence on pileup. This algorithm relies on the “pileup per particle identification” (PUPPI) method [15], and uses local shape information around each PF candidate in the event, event pileup properties, and tracking information to reduce the pileup dependence of jet and $p_T^{\text{miss}}$ observables.

The PUPPI $p_T^{\text{miss}}$ method employs a local shape variable $\alpha$, which is sensitive to differences between the collinear configuration of particles produced by the hadronization of quarks and gluons produced via QCD mechanisms and the soft diffuse radiation coming from pileup. The $\alpha$ variable is computed for each neutral particle, using the surrounding charged particles compatible with the PV within the tracker acceptance ($|\eta| < 2.5$), and using both charged and neutral particles in the region outside of the tracker coverage. The momenta of the neutral particles are then rescaled according to the probability that they originate from the PV deduced from the local shape variable [15], superseding the need for jet-based pileup corrections [16].

In CMS, the PUPPI algorithm is implemented using PF candidates. A different $\alpha$ definition is adopted for PF candidates within and outside the tracker acceptance. For a given PF candidate $i$, the $\alpha$ variable is defined as:

$$\alpha_i = \log \sum_{j \neq i, \Delta R_{ij} < 0.4} \left( \frac{p_T^j}{\Delta R_{ij}} \right)^2 \begin{cases} \text{for } |\eta_i| < 2.5, & j \text{ are charged PF candidates from PV} \\ \text{for } |\eta_i| > 2.5, & j \text{ are all kinds of reconstructed PF candidates} \end{cases},$$

(4.1)

where $j$ refers to neighboring charged PF candidates originating from the PV within a cone of radius $R$ in $\eta$-$\phi$ space around $i$, and $\Delta R_{ij}$ is the distance in $\eta$-$\phi$ space between the $i$ and $j$ PF candidates.
In addition, charged PF candidates not associated with the PV are used in the calculation if they satisfy $d_z < 0.3$ cm, where $d_z$ is the distance in $z$ between the track and the PV. In the absence of tracking coverage, the $j$ in eq. (4.1) extends to all PF candidates within a cone of radius 0.4.

A $\chi^2$ approximation

$$\chi^2_j = \frac{(\alpha_i - \bar{\alpha}_{PU})^2}{\text{RMS}^2_{PU}},$$

(4.2)
is used to determine the likelihood that a PF candidate came from pileup. In this equation, $\bar{\alpha}_{PU}$ is the median value of the $\alpha_i$ distribution for pileup particles in the event (pileup PF candidates) in the event, and $\text{RMS}_{PU}$ is the corresponding root-mean-square (RMS) of the $\alpha_i$ distribution. Within the tracker acceptance ($|\eta| < 2.5$), the values of $\bar{\alpha}_{PU}$ and $\text{RMS}_{PU}$ are calculated using all charged pileup PF candidates, and are ~ 3.5. Outside the tracker acceptance, the $\bar{\alpha}_{PU}$ and $\text{RMS}_{PU}$ are first estimated in the $|\eta| < 2.5$ region and then, with the aid of simulation, are extrapolated in the forward region by means of transfer factors. We define two forward regions: 2.5 < $|\eta|$ < 3 and $|\eta|$ > 3. The typical values of $\bar{\alpha}_{PU}$ and $\text{RMS}_{PU}$ in the 2.5 < $|\eta|$ < 3 region, are ~ 5.5 and ~ 2.5, respectively, whereas in the $|\eta|$ > 3 region, are ~ 4.5 and ~ 2, respectively. The $\chi^2$ variable in eq. (4.2) is transformed to a weight using:

$$w_i = F_{\chi^2, \text{NDF}=1}(\chi^2_j),$$

(4.3)

where $F_{\chi^2, \text{NDF}=1}$ is the cumulative distribution function, which approximates the $\chi^2$ distribution with one degree of freedom of all PF candidates in the event. The weights range from zero, for PF candidates originating from a pileup vertex, to close to one, for PF candidates originating from the PV. Charged PF candidates associated with the PV take the value of one. Once a weight per PF candidate is determined, the $p_T^{\text{miss}}$ can be computed using the sum of PF candidate four-vectors weighted by their $w_i$. In addition, the PUPPI-weighted PF candidates can be used as inputs to the jet clustering algorithm. No additional pileup corrections are applied to jets clustered from these weighted inputs. The results presented in this paper are based on jets without PUPPI corrections applied.

The $w_i$ are required to be larger than 0.01 and the minimum scaled $p_T$ of neutral PF candidates is required to be $w_i p_{T,i} > (A + B N_{\text{vtx}})$, where $N_{\text{vtx}}$ is the reconstructed vertex multiplicity. In this equation, $A$ and $B$ are adjustable parameters that depend on $\eta$. An optimization of the tunable parameters to achieve the best jet $p_T$ and $p_T^{\text{miss}}$ resolutions is performed separately for jets in the regions $|\eta| < 2.5$, 2.5 < $|\eta|$ < 3, and $|\eta|$ > 3. The resulting algorithm parameters are similar to those recommended in ref. [15], ranging from 0.2–2.0 and 0.015–0.8, for $A$ and $B$, respectively.

### 4.2 Calibration of $p_T^{\text{miss}}$

Examples of sources that can lead to an inaccurate estimation of $p_T^{\text{miss}}$ are the nonlinearity in the calorimeter response to hadrons, the minimum energy thresholds in the calorimeters, and the minimum $p_T$ thresholds and inefficiencies in track reconstruction. The estimation of $p_T^{\text{miss}}$ is improved by propagating the correction of the $p_T$ of the jets, $\bar{p}_T^{\text{corr}}$, described in ref. [11] to $p_T^{\text{miss}}$ in the following way:

$$\bar{p}_T^{\text{miss}} = p_T^{\text{miss, raw}} - \sum_{\text{jets}}(p_T^{\text{corr, jet}} - \bar{p}_T^{\text{corr, jet}}),$$

(4.4)
where $p_T^{\text{miss, raw}}$ is the uncorrected $p_T^{\text{miss}}$. The sum is over jets with $p_T > 15$ GeV. The results in section 9 show that this choice for the jet $p_T$ threshold reduces the contribution from jets from pileup interactions and gives a $p_T^{\text{miss}}$ response close to unity.

The corresponding threshold for LHC Run 1, with lower pileup, was 10 GeV [13, 14]. To remove the overlap of jets with electrons and photons, jets with more than 90% of their energy associated to the ECAL are not included in the sum. In addition, if a muon reconstructed using the outer tracking system overlaps with a jet, its four momentum is subtracted from the four momentum of the jet, and the JES correction [11] appropriate for the modified jet momentum is used in the $p_T^{\text{miss}}$ calculation.

The $p_T^{\text{miss}}$ relies on the accurate measurement of the reconstructed physics objects, namely muons, electrons, photons, hadronically decaying taus, jets, and unclustered energy ($E_U$). The $E_U$ is the contribution from the PF candidates not associated with any of the previous physics objects. Uncertainties related to the $p_T^{\text{miss}}$ measurement depend strongly on the event topology. To estimate the uncertainty in $p_T^{\text{miss}}$, the uncertainty in the momenta of all reconstructed objects is propagated to $p_T^{\text{miss}}$ by varying the estimate of each PF candidate flavor within its uncertainty and recomputing $p_T^{\text{miss}}$.

The JES uncertainties are less than 3% for jets within the tracker acceptance and 1–12% for those outside. The jet energy resolution (JER) uncertainties typically range between 5–20%. The muon energy scale uncertainty is 0.2%, and the electron and photon energy scale uncertainties are 0.6% in the barrel and 1.5% in the endcap. For hadronically decaying $\tau$ leptons the energy scale uncertainty is 1.2%. The uncertainties related to the leptons are small, compared to those from the JES and JER uncertainties, and are not considered in the results presented in this paper.

The uncertainty in the $E_U$ for LHC Run 1 was assessed as a uniform 10%, and it accounted for the differences observed between the data and the simulation [14]. The method is improved for LHC Run 2. The $E_U$ uncertainty is evaluated based on the momentum resolution of each PF candidate, which depends on the type of the candidate. A detailed description of the PF candidate calibration can be found in refs. [3, 6, 7]. The $p_T$ measurement for PF charged hadrons is dominated by the tracker resolution. For PF neutral hadrons, the $p_T$ resolution is dominated by the resolution of the HCAL. The ECAL resolution dominates the PF photon $p_T$ measurement, whereas HF intrinsic resolution dominates that for the PF particles in the HF. The largest contributions to the $E_U$ uncertainty are due to the PF neutral hadrons and PF candidates in the HF. Table 1 lists the functional forms of the resolutions of the PF candidate classes contributing to the $E_U$.

5 Simulated events

For comparison with data, simulated Monte Carlo (MC) events are produced for $\gamma$+jet and QCD multijet processes at leading order (LO) using the MadGraph5_aMC@NLO 2.2.2 [17] generator with up to four additional partons in the matrix element calculations. Samples for the $Z$+jets and $W$+jets processes are also produced at next-to-leading order (NLO) using the MadGraph5_aMC@NLO generator with up to two additional partons in the matrix element calculations. The top and single top quark background processes are simulated at NLO using powheg 2.0 and 1.0, respectively [18, 19]. The diboson samples ($WW$, $WZ$, and $ZZ$) are simulated at NLO using MadGraph5_aMC@NLO and powheg. A set of triboson samples ($WWW$, $WWZ$, $WZZ$, $ZZZ$) is simulated at NLO using MadGraph5_aMC@NLO. Lastly, the $Z\gamma$ and $W\gamma$ processes, collectively referred to as $V\gamma$ in the following, are simulated at LO with MadGraph5_aMC@NLO.

The MC samples produced using MadGraph5_aMC@NLO and powheg generators are interfaced with pythia 8.2 [20] using the CUETP8M1 tune [21] for the fragmentation, hadronization, and underlying event description. For the MadGraph5_aMC@NLO samples, jets from the matrix element calculations are matched to the parton shower following the MLM [22] (FxFx [23]) prescription for LO (NLO) samples. The NNPDF3.0 [24] parton distribution functions (PDFs) are used for all samples, with the order matching the matrix element calculations. The simulation of the interactions of all final-state particles with the CMS detector is done with Geant4 [25]. The simulated events are reconstructed using the same algorithms used for the data. The simulated events include the effects of pileup, with the number of additional pp interactions matching that observed in data. The average number of pileup interactions per proton bunch crossing is 23 for the data sample used in this analysis [26].

6 Event selection

In this paper, several final states are used to evaluate the performance of $p_T^{\text{miss}}$ reconstruction algorithms. Monojet and dijet samples are primarily used to study the performance of the algorithms developed to reject spurious events with anomalous $p_T^{\text{miss}}$, and are discussed in section 7. Dilepton and single-photon samples are used to study the $p_T^{\text{miss}}$ scale and resolution. A single-lepton sample, which contains events with a genuine $p_T^{\text{miss}}$ originating from a neutrino escaping without detection, is used to study the performance of the $p_T^{\text{miss}}$ reconstruction algorithm. Finally, the single-lepton and dilepton samples are also used to study the performance of the $p_T^{\text{miss}}$ significance. The selection criteria used for each sample are discussed below.

6.1 Monojet and dijet event samples

The events in the monojet sample are selected using triggers with requirements on both $p_T^{\text{miss}}$ and $H_T^{\text{miss}}$, where $p_T^{\text{miss}}$ is the magnitude of the vector $p_T$ sum of all PF candidates reconstructed at the trigger level, and $H_T^{\text{miss}}$ is the magnitude of the vector $p_T$ sum of jets with $p_T > 20\text{ GeV}$ and $|\eta| < 5.0$ reconstructed at the trigger level. Candidate events are required to have $p_T^{\text{miss}} > 250\text{ GeV}$, and the highest $p_T$ (leading) jet in the event is required to have $p_T > 100\text{ GeV}$ and $|\eta| < 2.4$. The background from processes including W bosons decaying leptonically is suppressed by imposing a veto on events containing one or more loose muons or electrons with $p_T > 10\text{ GeV}$, or $\tau$ leptons.
with \( p_T > 18 \) GeV. Events that contain a loose, isolated photon with \( p_T > 15 \) GeV and \( |\eta| < 2.5 \) are also vetoed. This helps suppress electroweak (EW) backgrounds with a photon radiated from an initial state parton. To reduce the contamination from top quark backgrounds, events are rejected if they contain a b-tagged jet with \( p_T > 20 \) GeV and \( |\eta| < 2.4 \).

The QCD multijet background with \( p_T^{\text{miss}} \) arising from mismeasurements of jet momenta is suppressed by requiring the angle between the \( \vec{p}_T^{\text{miss}} \) direction and each of the first four leading jets with \( p_T > 30 \) GeV is at least 0.5 radians. This selection facilitates the study of sources that could lead to artificially large (“spurious”) \( p_T^{\text{miss}} \) due a malfunctioning detector (section 7).

The events in the dijet sample are also selected using the \( p_T^{\text{miss}} \) and \( \mathcal{H}_T^{\text{miss}} \) triggers. Candidate events are required to have \( p_T^{\text{miss}} \) greater than 250 GeV and the leading (subleading) jet in the event is required to have \( p_T > 500 \) (200) GeV. As for the monojet sample, events with an identified loose lepton, photon, or a b-tagged jet are rejected.

6.2 Dilepton event samples

The dilepton samples are subdivided into two categories based on the flavor of the lepton, namely \( Z \to \mu^+\mu^- \) and \( Z \to e^+e^- \). The events for the \( Z \to \mu^+\mu^- \) sample are recorded using dimuon triggers that select events where the \( p_T \) of each of the two leading muons is above an asymmetric threshold. Candidate events are required to have both the leading (subleading) muon \( p_T \) greater than 25 (20) GeV and an invariant mass in the range of 80 to 100 GeV, compatible with the mass of the \( Z \) boson [27]. Events are vetoed if there is an additional muon or electron with \( p_T > 20 \) GeV. The events in the \( Z \to e^+e^- \) samples are recorded using dielectron triggers that have asymmetric selection requirements on the \( p_T \) of the two leading electrons. Candidate events are required to have the leading (subleading) electron \( p_T \) greater than 25 (20) GeV. As in the dimuon case, the invariant mass of the dielectron system is required to be in the range of 80 to 100 GeV. Events are vetoed if there is an additional muon or electron with \( p_T > 20 \) GeV. The spectrum of the \( Z \) boson transverse momentum, \( q_T \), is shown in figure 1 where only the statistical uncertainty in the simulated samples is considered because the dilepton energy resolution is very good.

6.3 Single-photon event sample

The events in the single-photon sample are selected using a set of isolated single-photon triggers with varying thresholds. The \( p_T \) thresholds of the triggers are 30, 50, 75, 90, 120, and 165 GeV. The first five of these triggers used different, luminosity dependent, L1 accept rates (prescales) during the data-taking periods. Candidate events are weighted based on the prescale values of the triggers.

Candidate events are required to have a tight photon with \( p_T > 50 \) GeV. To match the trigger conditions, the leading photon is further required to have the ratio of the energy deposited in a 3 x 3 crystal region of the ECAL, which is centered around the crystal containing an energy deposit greater than all of its immediate neighbors, to the energy of the entire deposit of the photon greater than 0.9.

The single-photon sample events are also required to have at least one jet with \( p_T \) greater than 40 GeV, and events with leptons with \( p_T \) greater than 20 GeV are vetoed. The photon \( q_T \) spectrum is shown in figure 2. As in figure 1, only the statistical uncertainty in the simulated samples is considered because the photon energy resolution is very good.
Figure 1. Upper panels: distributions of Z boson $q_T$ in $Z \rightarrow \mu^+ \mu^-$ (left) and $Z \rightarrow e^+ e^-$ (right) samples. The diboson contribution corresponds to processes with two electroweak bosons produced in the final state. The top quark contribution corresponds to the top pair and single top production processes. The last bin includes all events with $q_T > 385$ GeV. Lower panel: data to simulation ratio. The band corresponds to the statistical uncertainty in simulated samples.

Figure 2. Upper panel: distribution of the photon $q_T$ in the single-photon sample. The $V\gamma$, top quark contribution corresponds to the $Z\gamma$, $W\gamma$, top pair and single top production processes. The last bin includes all events with $q_T > 385$ GeV. Lower panel: data to simulation ratio. The band corresponds to the statistical uncertainty in the simulated samples.

6.4 Single-lepton event samples

The single-lepton samples are subdivided into two categories based on the flavor of the lepton. These events in the single-muon (single-electron) sample are selected using triggers based on the $p_T$ and the isolation of the muon (electron). Candidate events are required to have a tight muon (electron) with $p_T$ greater than 25 (26) GeV. Events with an additional lepton with $p_T$ greater than 10 GeV, or with a b-tagged jet, are rejected.

These single-lepton samples consist mainly of W+jets events. One source of background stems from QCD multijet events containing a jet misidentified as a lepton. The simulation indicates that
the magnitude of this background is small. However, since the uncertainties in simulating this background can be significant, we use a data control region to estimate it. The data control sample is selected by inverting the requirement on the relative isolation of the lepton and is dominated by QCD multijet events. The normalization of this background is then corrected by comparing the observed and expected number of events in the data control sample. Other processes are estimated from simulation.

The spectrum of the W boson transverse momentum $q_T$ is shown in figure 3. In contrast to figures 1 and 2, the effects of the systematic uncertainties from the JES, JER, and $E_U$ are sizable and are included in addition to the systematic uncertainty from the limited statistics in the simulated samples.

7 Anomalous $p_T^{\text{miss}}$ events

Anomalous high-$p_T^{\text{miss}}$ events can arise because of a variety of reconstruction failures or malfunctioning detectors. In the ECAL, spurious deposits may appear due to noisy sensors in the ECAL photodetectors, or from genuine showers with noncollision origins, such as those caused by the production of muons when beam protons undergo collisions upstream of the detector (beam halo). An additional source of artificial $p_T^{\text{miss}}$ is the presence of dead cells, leading to underestimation of the energy. In the HCAL, spurious energy can arise from noise in the hybrid photodiode (HPD) and in the readout box (RBX) electronics, as well as from direct particle interactions with the light guides and photomultiplier tubes of the HF. These sources have been studied extensively in the data collected in LHC Run 1 [13, 14]. Algorithms (filters) developed during LHC Run 1 to identify and suppress events with anomalously high $p_T^{\text{miss}}$ are also used for this data (LHC Run 2) with the necessary modifications for the upgraded detector [28] and the different data-taking conditions. An additional set of filters was also developed during this run to identify new sources of artificial $p_T^{\text{miss}}$. Details of the various filters are given below.
• **HCAL filters**

The geometrical patterns of HPD or RBX channels as well as the pulse shape and timing information are used by various HCAL barrel and endcap (HBHE) algorithms to identify and eliminate noise. These filter algorithms operate both in “noise filtering” and “event filtering” modes. In the noise filtering mode, the anomalous energy deposits are removed from the event reconstruction; in the filtering mode, the event is removed from the data set. In addition, there is an isolation-based noise filter that utilizes a topological algorithm, where energy deposits in HCAL and ECAL are combined and compared with measurements from the tracker to identify isolated anomalous activity in HB/HE. An additional noise filter based on pulse shapes uses information at the cluster reconstruction level and searches for uncharacteristic noise signals in the HB/HE HPD channels. It relies on the known pulse shapes of HPDs, and is similar the RBX pulse shape filters [29], but explicitly corrects for the presence of in-time and out-of-time pileup when testing for anomalous pulse shapes.

• **ECAL filters**

For the ECAL, much of the electronics noise and spurious signals from particle interactions with the photodetectors is removed during reconstruction using the topological and timing information. The remaining effects that lead to high-$p_T^{\text{miss}}$ signatures, such as anomalously high energy deposits in supercrystals, and the lack of information for channels that have nonfunctioning readout electronics, are removed through dedicated noise filters.

During this data-taking run (LHC Run 2), five ECAL endcap supercrystals produced large, anomalous pulses, leading to spurious $p_T^{\text{miss}}$. These crystals are removed from the readout, and their energies are not considered. Furthermore, in about 0.7% of ECAL towers (i.e. $5 \times 5$ ECAL crystals), the crystal-by-crystal information is not available. The trigger primitive (TP) [5] information, however, is still available, and is used to estimate the energy. The TP information saturates above 127.5 GeV. Events with a TP close to saturation in any of these ECAL towers are removed.

• **Beam halo filter**

Machine-induced backgrounds, especially beam halo, can cause anomalously large $p_T^{\text{miss}}$. Beam halo particles travel nearly parallel to the collision axis and can sometimes interact in the calorimeters, leaving energy deposits along a line with constant $\phi$. In addition, interactions in the CSC, a subdetector with good reconstruction performance for both collision and noncollision muons, will often be in line with the calorimeter deposits. The beam halo filter was redesigned for LHC Run 2. In LHC Run 1 the filter was based solely on information from the CSC. However, the LHC Run 2 filter exploits information from both the CSC and the calorimeters, resulting in a significant improvement in performance.

• **Reconstruction filters**

An additional source of anomalous high-$p_T^{\text{miss}}$ events during LHC Run 2 was poor reconstruction of muons during the muon-tracking iteration step [4]. If a high-$p_T$ track has a low quality reconstruction, it could contribute to $p_T^{\text{miss}}$ either as a poorly reconstructed PF muon, or as a poorly reconstructed PF charged hadron. The poorly reconstructed muons and
charged hadrons are identified based on the ratio of the relative $p_T$ uncertainty of the track $p_T$, determined by the Tune-P algorithm [4], or the inner track $p_T$. Once a poorly reconstructed muon or a charged hadron is identified, dedicated filters are designed to reject these events.

Figure 4 shows a comparison of the $p_T^{\text{miss}}$ (left) and jet $\phi$ (right) distributions before and after the application of the event filters for the dijet and monojet samples, respectively. The anomalous events with large $p_T^{\text{miss}}$ in the dijet sample are mostly due to electronic noise in the calorimeters. The jet $\phi$ distribution in the monojet sample is used to validate the performance of the beam halo filter. The angular distribution of beam halo events is dictated by the shape of the LHC tunnel and the beamline elements [30] and results in an excess of events with jet $\phi \approx 0$ or $\phi \approx \pi$. These events are removed by the beam halo filter. In both samples, the simulated $p_T^{\text{miss}}$ and jet $\phi$ distributions are in good agreement with data after the application of all the filters. The event filters are designed to identify more than 85–90% of the spurious high-$p_T^{\text{miss}}$ events with a mistag rate of less than 0.1%.

In addition to the event filtering algorithms, a jet identification selection is imposed, which requires the neutral hadron energy fraction of a jet be less than 0.9. This selection rejects more than 99% of the noise jets, independent of jet $p_T$, with a negligible mistag rate.

8 Performance of $p_T^{\text{miss}}$ reconstruction at the trigger level

At L1, $p_T^{\text{miss}}$ is computed at the global calorimeter trigger (GCT) level [5], which is the last stage of the L1 calorimeter trigger chain. The trigger-level quantities computed by the GCT use data from the regional calorimeter trigger (RCT) [5], which receives the transverse energies, $E_T$, and quality flags from ECAL and HCAL. At GCT level, the $p_T^{\text{miss}}$ is calculated by summing the regional transverse energy values and rotating the resulting vector by 180°. A more detailed description can be found in [5]. Although the RCT coverage could be extended to $|\eta| < 5.0$, the $p_T^{\text{miss}}$ algorithm at L1 only uses information from trigger towers within $|\eta| < 3.0$, due to the bandwidth restrictions of the trigger system.
Two reconstruction algorithms are used at the HLT. A \( p_T^{\text{miss}} \) variable using only information from the calorimeters (Calo \( p_T^{\text{miss}} \)) is used as a prefilter to a more complex, PF-based \( p_T^{\text{miss}} \) reconstruction. The Calo \( p_T^{\text{miss}} \) is computed by taking the negative vector \( E_T \) sum of all calorimeter towers, whereas PF \( p_T^{\text{miss}} \) is based on the negative vector \( p_T \) sum of all reconstructed PF jets without a \( p_T \) requirement, as in the case of the offline reconstruction algorithms.

To maintain the lowest possible thresholds for the \( p_T^{\text{miss}} \) triggers, event filtering algorithms are applied at the trigger level. In contrast to the offline case, at the trigger level the calorimeter energy deposits flagged as being consistent either with HB/HE noise or beam halo are removed from the energy sum, and \( p_T^{\text{miss}} \) is recomputed. The noise filtering algorithms used at the HLT are fully efficient with respect to the offline filtering algorithms, and reduce the rate of \( p_T^{\text{miss}} \) triggers by up to a factor of 2.5, depending on the \( p_T^{\text{miss}} \) threshold.

As with the offline reconstruction, HLT PF \( p_T^{\text{miss}} \) is calibrated by correcting the \( p_T \) of the jets using the jet energy corrections. In contrast to the offline calibration, the corrections for the jets are only propagated to the \( p_T^{\text{miss}} \) if the jet \( p_T \) is above 35 GeV. The performance of the \( p_T^{\text{miss}} \) triggers is measured in single-electron samples. The efficiency for each trigger-level \( p_T^{\text{miss}} \) object type is shown in figure 5. The calibrated \( p_T^{\text{miss}} \) at the HLT level yields an improved efficiency at lower \( p_T \). As a result, online trigger thresholds are set to higher values, typically \( \gtrsim 170 \) GeV, yielding the same performance offline, for up to 10% rate reduction depending on the \( p_T^{\text{miss}} \) threshold.

![Figure 5](https://example.com/figure5.png)

**Figure 5.** The \( p_T^{\text{miss}} \) trigger efficiency as a function of offline \( p_T^{\text{miss}} \), measured using a single-electron sample. The efficiency of each reconstruction algorithm, namely the L1, the calorimeter, and the PF-based \( p_T^{\text{miss}} \) algorithms, is shown separately. The numbers in parentheses correspond to the HLT \( p_T^{\text{miss}} \) thresholds. The logical OR of the L1 \( p_T^{\text{miss}} \) triggers with requirements on \( p_T^{\text{miss}} \) greater than 50, 60, 70, 80, 90, 100 and 120 GeV are used.

9 Performance of \( p_T^{\text{miss}} \) algorithms

A well-measured Z/\( \gamma \) boson provides a unique event axis and a precise momentum scale. To this end, the response and resolution of \( p_T^{\text{miss}} \) is studied in samples with an identified Z boson decaying to a pair of electrons or muons, or with an isolated photon. Such events should have little or no genuine \( p_T^{\text{miss}} \), and the performance is measured by comparing the momenta of the vector boson to
that of the hadronic recoil system. The hadronic recoil system is defined as the vector $p_T$ sum of all PF candidates except for the vector boson (or its decay products in the case of the Z boson decay). In figure 6 the kinematic representations of the transverse momenta of the vector boson and the hadronic recoil, $\vec{q}_T$ and $\vec{u}_T$, are shown. Momentum conservation in the transverse plane imposes $\vec{q}_T + \vec{u}_T + \vec{p}_T^{\text{miss}} = 0$.

The components of the hadronic recoil parallel and perpendicular to the boson axis are denoted by $u_\parallel$ and $u_\perp$, respectively. These are used to study the $p_T^{\text{miss}}$ response and resolution. Specifically, the mean of the distribution of the magnitude of $\vec{u}_\parallel + \vec{q}_\parallel$, denoted as $u_\parallel + q_T$, is used to estimate the $p_T^{\text{miss}}$ response, whereas the RMS of the $u_\parallel + q_T$ and $u_\perp$ distributions are used to estimate the resolution of $u_\parallel$ and $u_\perp$, denoted by $\sigma(u_\parallel)$ and $\sigma(u_\perp)$, respectively. The response of $p_T^{\text{miss}}$ is defined as $-\langle u_\parallel \rangle / \langle q_T \rangle$ where $\langle \rangle$ indicates the mean of the distributions.

An alternative method insensitive to tails in the distributions is also used. The $u_\parallel + q_T$ and $u_\perp$ are parametrized using a Voigtian function, defined as the convolution of a Breit-Wigner and a Gaussian distribution. The results obtained with the alternative method agree within 2% with those obtained using the primary method (i.e., mean/RMS), indicating that the effect of the non-Gaussian tails on the $p_T^{\text{miss}}$ performance is small. In the following sections, the performance of the PF and PUPPI $p_T^{\text{miss}}$ algorithms is shown using the primary method.

9.1 Performance of the PF $p_T^{\text{miss}}$ algorithm

The PF $p_T^{\text{miss}}$ distributions in dilepton and photon samples are shown in figure 7. The data distributions are modeled well by the simulation.

The $p_T^{\text{miss}}$ resolution in these events is dominated by the resolution of the hadronic activity, since the momentum resolution for leptons and photons is $\sigma(p_T)/p_T \lesssim 1.5\%$ [4, 7], compared to 5–20% for the jet momentum resolution [11]. The uncertainty shown in the figures includes uncertainties in the JES, the JER, and the energy scale of unclustered particles, added in quadrature. The increase in the uncertainty band around 40 GeV is related to the JES and the JER sources in events with at least one jet and no genuine $p_T^{\text{miss}}$. For processes with genuine $p_T^{\text{miss}}$, e.g., top quark background, are present, the uncertainty is somewhat smaller.

Distributions of $u_\parallel + q_T$ and $u_\perp$ in $Z \rightarrow \mu^+\mu^-$, $Z \rightarrow e^+e^-$ and $\gamma$+jets events are shown in figure 8. The kinematic definition of $u_\parallel$ dictates that for processes with no genuine $p_T^{\text{miss}}$, $u_\parallel$ is balanced with the boson $q_T$. Therefore, the vectorial sum of $u_\parallel$ and $q_T$ results in a symmetric distribution, centered at zero; any deviations from this behavior imply imperfect calibration of $p_T^{\text{miss}}$. 

![Figure 6. Illustration of the Z boson (left) and photon (right) event kinematics in the transverse plane. The vector $\vec{u}_T$ denotes the vectorial sum of all particles reconstructed in the event except for the two leptons from the Z decay (left) or the photon (right).]
Events with genuine $p_T^{\text{miss}}$ due to the presence of neutrinos, $u_\parallel$ and $q_T$ are not balanced, leading to an asymmetric distribution. The $u_\perp$ distribution is symmetric with a mean value of zero. This symmetry is due to the assumed isotropic nature of the energy fluctuations of the detector noise and underlying event. Good agreement is observed between data and simulation for all the distributions.

Figure 7 shows the $p_T^{\text{miss}}$ response as a function of $q_T$, in data and simulation, in $Z \rightarrow \mu^+\mu^-$, $Z \rightarrow e^+e^-$, and photon events. The response reaches unity for boson $p_T > 100$ GeV. Deviations from unity indicate imperfect calibration of the hadronic energy scale. The underestimation of the hadronic response observed at smaller $q_T \lesssim 100$ GeV is due to the significant contribution of the uncalibrated component of $p_T^{\text{miss}}$, which mainly consists of jets with $p_T < 15$ GeV and unclustered particles. There is no dedicated response correction for the $E_U$. The response of $p_T^{\text{miss}}$ agrees for all three samples within 2%; a significant improvement with respect to the results from the LHC Run 1 [13, 14]. The “footprint removal” discussed in section 3 plays an important role in this improvement. The residual response difference among the samples stems from the different mechanism used to differentiate muons, electrons, and photons from jets used in the correction of
Figure 8. Distribution of $u_T + q_T$ and $u_T$, components of the hadronic recoil, in data (filled markers) and simulation (solid histograms), in the $Z \rightarrow \mu^+\mu^−$ (upper), $Z \rightarrow e^+e^−$ (middle), and $\gamma + \text{jets}$ (lower) samples. The first and the last bins include all events below $-195$ and above $+195$, respectively. The points in the lower panel of each plot show the data to simulation ratio. The systematic uncertainties due to the JES, the JER, and variations in the $E_T$, are added in quadrature and represented by the shaded band.
the $p_T^{\text{miss}}$, as discussed in section 4.2. Simulation studies have shown that in the case of electrons and photons, a small fraction ($\lesssim 10\%$) of jets survive the differentiation criteria yet overlap with prompt electrons and photons. As a result, these jets wrongly contribute to the $p_T^{\text{miss}}$ calibration, leading to a 1–2\% lower response in the electron and photon channels. Future studies will aim at further improving the electron/photon and jet differentiation mechanism. Overall, we observe good agreement between data and simulation.

Figure 9. Upper panel: response of $p_T^{\text{miss}}$, defined as $-\langle u_\parallel \rangle/\langle q_T \rangle$, in data in $Z \rightarrow \mu^+\mu^-$ (blue), $Z \rightarrow e^+e^-$ (red), and $\gamma$+jets (green) events. Lower panel: ratio of the $p_T^{\text{miss}}$ response in data and simulation. The band corresponds to the systematic uncertainties due to the JES, the JER, and variations in the $E_U$ added in quadrature, estimated from the $Z \rightarrow e^+e^-$ sample.

The resolution of $p_T^{\text{miss}}$ for the $u_\parallel$ and $u_\perp$ components of the hadronic recoil as a function of $q_T$ is shown in figure 10 (upper row). To compare the resolution of $p_T^{\text{miss}}$ consistently across the samples, the resolution in each sample is corrected for the differences observed in the response. The correction has a negligible impact on the results. The resolutions measured in different samples are in good agreement. The relative resolution, both in $u_\parallel$ and $u_\perp$, improves as a function of $q_T$ because of the improved energy resolution in the calorimeters. Furthermore, due to the isotropic nature of energy fluctuations stemming from detector noise and the underlying event, the dependence of the resolution of $u_\perp$ on $q_T$ is smaller than for $u_\parallel$. For $q_T > 200$ GeV, the $p_T^{\text{miss}}$ resolution is $\approx 13\%$ and $\approx 9\%$, for $u_\parallel$ and $u_\perp$, respectively.

The resolution of the $u_\parallel$ and $u_\perp$ components of the hadronic recoil as a function of $N_{\text{vtx}}$, are shown in figure 10 (middle row). The resolutions measured in different samples, and in data and simulation, are in good agreement. However, the resolution shows strong dependence on $N_{\text{vtx}}$, since pileup mitigation techniques are employed only for the PF jets, but not for the PF $p_T^{\text{miss}}$ algorithm.
The resolution is parametrized as a function of $N_{\text{vtx}}$:

\[ f(N_{\text{vtx}}) = \sqrt{\sigma_c^2 + \frac{N_{\text{vtx}}}{0.70} \sigma_{\text{PU}}^2}, \quad (9.1) \]

where $\sigma_c$ is the resolution term induced by the hard scattering interaction and $\sigma_{\text{PU}}$ is the average contribution to the resolution from each additional pileup interaction. The factor 0.70 accounts for the vertex reconstruction efficiency [31]. Results of the parametrization for the $u_\parallel$ and $u_\perp$ components are given in table 2. Good agreement is observed between data and simulation and no additional corrections are used for the $p_T^{\text{miss}}$ calibration. Every additional pileup vertex degrades the resolution of each component by 3.8–4.0 GeV.

Lastly, figure 10 (lower row) shows an alternative parametrization of the resolution of $u_\parallel$ and $u_\perp$ as a function of the scalar $p_T$ sum of all PF candidates ($\sum E_T$). The resolutions measured in different samples, and in data and simulation, are in good agreement. The relative $p_T^{\text{miss}}$ resolution improves with increasing $\sum E_T$, driven by the amount of the activity in the calorimeters. The resolution in different samples is parametrized as:

\[ f\left(\sum E_T\right) = \sigma_0 + \sigma_s \sqrt{\sum E_T}, \quad (9.2) \]

where $\sigma_0$ is the resolution term induced by intrinsic detector noise and $\sigma_s$ is the stochastic resolution term. Results of the parametrization for the $u_\parallel$ and $u_\perp$ components are given in table 3. The results are found to be consistent between data and simulation and no additional corrections are used for the $p_T^{\text{miss}}$ calibration.

9.2 Performance of the PUPPI $p_T^{\text{miss}}$ algorithm

The PUPPI $p_T^{\text{miss}}$ distributions in the dilepton samples are shown in figure 11. The data distributions are modeled well by the simulation, in both the muon and the electron channels. As in the case of PF $p_T^{\text{miss}}$, the $p_T^{\text{miss}}$ resolution in these events is dominated by the resolution of the hadronic activity, but the PUPPI-weighted PF candidates yield improved resolution for jets compared to the PF case. This is also reflected in the uncertainty shown in the figures, which includes the uncertainties due to JES and JER, and the energy scale of the unclustered particles.

Figure 11. Upper panels: distributions of PUPPI $p_T^{\text{miss}}$ in $Z \rightarrow \mu^+\mu^-$ (left) and $Z \rightarrow e^+e^-$ (right) events. The last bin includes all events with $p_T^{\text{miss}} > 195$ GeV. Lower panels: data-to-simulation ratio. The band corresponds to the systematic uncertainties due to the JES, the JER, and variations in the $E_T$ added in quadrature, estimated from the $Z \rightarrow e^+e^-$ sample.
The distributions in $Z \to \mu^+\mu^-$ and $Z \to e^+e^-$ events of the vectorial sum $u_{\parallel} + q_T$ and of $u_\perp$ using PUPPI $p_T^{\text{miss}}$, are shown in figure 12. Following the same arguments as in the PF $p_T^{\text{miss}}$ case, in events with no genuine $p_T^{\text{miss}}$ the vectorial sum of $u_q$ and $q_T$ is symmetric around zero, whereas for processes with genuine $p_T^{\text{miss}}$ an asymmetric behavior is observed. The distribution of $u_\perp$ is symmetric around zero. Simulation describes data well for all distributions.

Figure 12. Upper panels: distributions of the $u_{\parallel} + q_T$ and $u_\perp$ components of the hadronic recoil, in data (filled markers) and simulation (solid histograms), for the $Z \to \mu^+\mu^-$ (upper) and $Z \to e^+e^-$ (lower) events. The first and the last bins include all events below -195 and above +195, respectively. Lower panel: data-to-simulation ratio. The band corresponds to the systematic uncertainties due to the JES, the JER, and variations in the $E_U$ added in quadrature, estimated from the $Z \to e^+e^-$ sample.

Figure 13 shows the PUPPI $p_T^{\text{miss}}$ response as a function of $q_T$ for data and simulation in $Z \to \mu^+\mu^-$ and $Z \to e^+e^-$ events. The response rises to unity for $Z \to \mu^+\mu^-$ at a $Z$ boson $p_T$ of 150 GeV, whereas for PF $p_T^{\text{miss}}$ the reaches unity at 100 GeV. The slower rise of the response to unity is due to the removal of PF candidates that are wrongly associated with pileup interactions by the PUPPI algorithm. As in PF $p_T^{\text{miss}}$, there is no response correction for the $E_U$ in the PUPPI $p_T^{\text{miss}}$, which results in an underestimated response at low $q_T$. The response of $p_T^{\text{miss}}$ agrees for the different samples within 2%.

The resolution of the PUPPI $p_T^{\text{miss}}$ for the $u_{\parallel}$ and $u_\perp$ components of the hadronic recoil as a function $N_{\text{e}x}$ is shown in figure 14. To compare the resolution of $p_T^{\text{miss}}$ consistently across the
samples, the resolution in each sample is corrected for the differences observed in the scale. The resolutions measured in different samples are in good agreement. In figure 15, the results obtained for the case of PUPPI $p_T^{\text{miss}}$ are overlaid with the ones obtained using PF $p_T^{\text{miss}}$. Compared to the case of PF $p_T^{\text{miss}}$, the resolutions show a much reduced dependence on the number of pileup interactions.

The resolutions in different samples are parametrized using eq. (9.1), and the results of the parameterization are given in table 4. Good agreement is observed between data and simulation and no additional corrections are used in the $p_T^{\text{miss}}$ calibration. Each additional pileup interaction degrades the resolution of each component by up to 2 GeV. This degradation in resolution corresponds to half of that observed in the case of PF $p_T^{\text{miss}}$.

### Table 4. Parameterization results of the resolution curves for PUPPI $u_\parallel$ and $u_\perp$ components as a function of $N_{\text{vtx}}$. The parameter values for $\sigma_c$ are obtained from data and simulation, and the values for $\sigma_{\text{PU}}$ are obtained from data, along with the ratio $R_{\text{PU}}$ of data and simulation. The uncertainties displayed for both the components are obtained from the fit, and for simulation the JES, the JER, and $E_T$ uncertainties are added in quadrature.

Lower panels: data-to-simulation ratio. The systematic uncertainties due to the JES, the JER, and variations in the $E_U$ are added in quadrature and represented by the shaded band.

9.3 Performance of $p_T^{\text{miss}}$ in single-lepton samples

Also single-lepton events, which contain genuine $p_T^{\text{miss}}$, are utilized to study the performance of the $p_T^{\text{miss}}$ algorithms. In events with a W boson, the magnitude of the $p_T^{\text{miss}}$ is approximately equal to the $p_T$ of the lepton, and its resolution is dominated by the hadronic recoil.
In figure 16, the PF and PUPPI \( p_T\) distributions are compared in single-muon and -electron samples, where the normalization of the QCD multijet background is corrected using the method discussed in section 6.4. A larger discrimination between events with and without genuine \( p_T\) is observed for the PUPPI \( p_T\) algorithm.

The transverse mass \( (M_T)\) of the lepton-\( p_T\) system is compared between the algorithms, as shown in figure 17. The \( M_T\) of the system is computed as:

\[
M_T = \sqrt{2p_T^{\text{lepton}} p_T^{\text{miss}} (1 - \cos \Delta \phi)},
\]

(9.3)

where \( p_T^{\text{lepton}}\) is the \( p_T\) of the lepton, and \( \Delta \phi\) is the angle between \( p_T^{\text{lepton}}\) and \( p_T^{\text{miss}}\). As in the \( p_T^{\text{miss}}\) case, the PUPPI algorithm has a better discrimination between events with and without genuine \( p_T^{\text{miss}}\). In addition, the spread of the Jacobian mass peak is smaller when \( M_T\) is computed using PUPPI \( p_T^{\text{miss}}\). The summary of the mean and the spread of the Jacobian mass peak, calculated in simulated W+jets events, is provided in table 5. Utilizing PUPPI \( p_T^{\text{miss}}\) for the \( M_T\) calculation results in a 10–15% relative improvement in the resolution of the Jacobian mass peak with respect to PF \( p_T^{\text{miss}}\).
Figure 17. The PF (left) and PUPPI (right) $M_T$ distribution are shown for single-muon (upper) and single-electron (lower) events. The last bin includes all events with $M_T > 135$ GeV. In all the distributions, the lower panel shows the ratio of data to simulation. The systematic uncertainties due to the JES, the JER, and variations in the $E_U$ are added in quadrature and represented by the shaded band.

10 The $p_T^{\text{miss}}$ significance

The ability to distinguish between events with genuine $p_T^{\text{miss}}$ and those with spurious $p_T^{\text{miss}}$ is important for analyses targeting signatures with weakly interacting particles. The $p_T^{\text{miss}}$ significance variable, denoted by $S$, quantifies the degree of compatibility of $p_T^{\text{miss}}$ with zero on an event-by-event basis, and it is computed using all clustered objects and the $E_U$ in each event. A factorized approach leads to the construction of a significance variable that is applicable to a variety of event topologies. The variable is described in detail in refs. [13, 14]. Here we give an overview of updates and performance studies conducted using the 13 TeV data set.

The significance is defined as the log-likelihood ratio

$$S \equiv 2 \ln \left( \frac{L(\vec{\epsilon} = \sum \vec{\epsilon}_i)}{L(\vec{\epsilon} = 0)} \right),$$

where $\vec{\epsilon}$ is the true $p_T^{\text{miss}}$ and $\sum \vec{\epsilon}_i$ is the observed $p_T^{\text{miss}}$. In the numerator, we evaluate the likelihood that the true value of $p_T^{\text{miss}}$ equals the observed value, while the denominator corresponds
that is not included in a jet are summed vectorially, and the resulting momentum is assigned to 

Table 5. The summary of the mean and the spread of the Jacobian mass peak in the $M_T$ distribution in single-lepton events for PF and PUPPI $p_T^{\text{miss}}$ algorithms. The results are obtained using simulated W+jets events.

</table>

To the null hypothesis, i.e., that the true $p_T^{\text{miss}}$ is zero. To a very good approximation the likelihood $\mathcal{L}(\vec{\epsilon})$ has the form of a Gaussian distribution. The significance can be therefore written as:

\[
S = \left( \sum \vec{\epsilon}_i \right) V^{-1} \left( \sum \vec{\epsilon}_i \right), \tag{10.2}
\]

where $V$ is the $2 \times 2$ $p_T^{\text{miss}}$ covariance matrix. In this formulation, $S$ is conveniently a $\chi^2$ variable with two degrees of freedom (one degree of freedom each for the $x$- and $y$-axis components of $p_T^{\text{miss}}$) for events with zero true $p_T^{\text{miss}}$.

The covariance matrix $V$ in eq. (10.2) models the $p_T^{\text{miss}}$ resolution in each event. It is constructed by propagating the individual resolutions of the objects entering the $p_T^{\text{miss}}$ sum. In most cases, the $p_T^{\text{miss}}$ resolution captured in $V$ is primarily determined by the hadronic components of the event, which includes jets with $p_T > 15$ GeV and the $E_L$. Jets enter the total covariance $V$ with an individual covariance of the form:

\[
U = \begin{pmatrix}
\sigma_{\phi}^2 & 0 \\
0 & p_T^2 \sigma_{\phi}^2
\end{pmatrix}, \tag{10.3}
\]

where the quantities $\sigma_{\phi}$ and $\sigma_{\phi}$ are measured and then recalculated based on a combination of simulation and data control samples, as explained in ref. [14]. The momenta of the PF candidates $i$ that is not included in a jet are summed vectorially, and the resulting momentum is assigned to a single pseudo-object i.e., $\vec{p}_T = \sum_i \vec{p}_{iT}$. The resolution of this pseudo-object is parameterized by the scalar $p_T$ sum of its constituents:

\[
\sigma_{uc}^2 = \sigma_0^2 + \sigma_x^2 \sum_{i=1}^{n} |\vec{p}_{iT}|, \tag{10.4}
\]

where the values of $\sigma_0^2$ and $\sigma_x^2$ are determined using control samples in data, as explained in ref. [14]. The resolution of this object is assumed to be isotropic in the transverse plane of the detector. The finite (small) resolution of electrons and muons is negligible, compared to the hadronic component of the event, and hence their contribution to $V$ is neglected.
10.1 Unclustered energy studies

The unclustered PF candidates are combined into a pseudo-object. Its resolution should be isotropic in the transverse plane, and proportional to the magnitude of the \( p_T \) of the pseudo-object. This approach, called the “standard” method of \( S \) in what follows, is motivated by its simplicity, and shows good agreement between data and simulation. The diagonal elements of the contribution of the \( E_U \) to the covariance matrix are given by eq. (10.4).

During the data-taking run, an alternative method to obtain the covariance matrix was explored, the so-called “jackknife technique” [32, 33]. The jackknife technique allows the estimation of a covariance matrix that is not necessarily isotropic, and also includes off-diagonal elements. The covariance matrix is calculated using the “delete-1 method”, in which a single PF candidate is removed. This approach leads to \( N - 1 \) samples per event, with \( N \) the total numbers of constituents contributing to the \( E_U \). The covariance matrix takes the form:

\[
\hat{V}_{ij} = \frac{N - 1}{N} \sum_{k=1}^{N} (p_{ki}^k - \bar{p}_i)(p_{kj}^k - \bar{p}_j),
\]

(10.5)

where \( k \) is the removed candidate, \( p_{ki}^k \) and \( p_{kj}^k \) are x and y components of the \( E_U \) calculated after removing the \( k \)-th candidate, whereas the indexes i and j both span x and y. The \( \bar{p}_i \) and \( \bar{p}_j \) are mean values of x and y components of the \( E_U \) over all samples, defined as:

\[
\bar{p}_{i,j} = \frac{1}{N} \sum_{k=1}^{N} p_{i,j}^k.
\]

(10.6)

Again, the resolution is scaled by the parameters tuned in data and simulated samples, referred to as \( a_x \) and \( a_y \). The parameters are determined following a similar approach as in the standard method of \( S \). The resolutions of the components of the \( E_U \) are then defined as

\[
\sigma_{x}^2 = a_x^2 \hat{V}_{xx},
\]

\[
\sigma_{xy}^2 = a_x a_y \hat{V}_{xy},
\]

\[
\sigma_{y}^2 = a_y^2 \hat{V}_{yy},
\]

(10.7)

10.2 Performance evaluation

The discrimination power between events with genuine \( p_T^{\text{miss}} \) (signal) and those without (background), of the two versions of \( S \), the standard and the jackknife, and the \( p_T^{\text{miss}} \) algorithms, is compared in terms of receiver operating characteristic (ROC) curves. The results are shown in figure 18 using simulated dimuon events (a sample dominated by events with no genuine \( p_T^{\text{miss}} \)) and single-electron events (a sample dominated by events with genuine \( p_T^{\text{miss}} \)). No significant difference between the two \( S \) versions is observed. Both versions of \( S \) offer better signal-to-background separation than \( p_T^{\text{miss}} \). For example, choosing a working point with 1% background efficiency the \( S \) variables offer 5% higher signal efficiency than \( p_T^{\text{miss}} \). For the remainder of the section, we focus only on the standard version of \( S \).

The performance of \( S \) is evaluated in data using dilepton and single-lepton events. The results are displayed in figures 19 and 20, respectively, for different jet multiplicities. In figure 19, where
events with no genuine $p_T^{\text{miss}}$ dominate, the core of the $S$ spectrum follows an ideal $\chi^2$ distribution. For large values of $S$ the spectrum begins to deviate from a perfect $\chi^2$ distribution as the processes with genuine $p_T^{\text{miss}}$ become important. This deviation also has contributions from the nonGaussian tails of the jet $p_T$ resolution function, which are not considered in eq. (10.2). A detailed discussion of the treatment of nonGaussian resolutions can be found in [14].

The stability of $S$ against pileup is studied using dimuon and single-electron events. Figure 21 displays the average $S$ as a function of $N_{\text{vtx}}$. In the dimuon sample, dominated by events with no genuine $p_T^{\text{miss}}$, the value of $S$ is robust against pileup, with an average value of $\sim 2$, as expected for a $\chi^2$ variable with two degrees of freedom. This behavior can be explained qualitatively with the following arguments. In the case of events with no genuine $p_T^{\text{miss}}$, the contribution of pileup affects in a similar manner both $p_T^{\text{miss}}$ and the variance of $p_T^{\text{miss}}$, since both are dominated by the hadronic resolution. This results in an essentially constant value of $S$ which does not depend on the number of pileup interactions. However, in events with genuine $p_T^{\text{miss}}$, as in the single-electron sample, pileup has a small impact on $p_T^{\text{miss}}$, whereas the impact on the resolution in $p_T^{\text{miss}}$ is similar to the case of no genuine $p_T^{\text{miss}}$, leading to a decrease of $S$ as pileup increases. This results in a degradation in the performance of $S$ when $N_{\text{vtx}}$ is large.

11 Summary
The performance of missing transverse momentum ($p_T^{\text{miss}}$) reconstruction algorithms in events with or without genuine $p_T^{\text{miss}}$ is presented. The results are based on a sample of proton-proton collisions recorded by the CMS experiment at $\sqrt{s} = 13$ TeV in 2016, corresponding to an integrated luminosity of $35.9 \, \text{fb}^{-1}$.

The performance of algorithms used to identify and remove events with anomalous $p_T^{\text{miss}}$ is also studied in events with one or more jets. The scale and resolution of $p_T^{\text{miss}}$ is determined using
Figure 19. Distributions of $S$ in data and simulation in dimuon (upper) and dielectron (lower) samples, for events with zero jet (left) and $\geq 1$ jet (right). The last bin includes all events with $S > 48$. The red straight line corresponds to a $\chi^2$ distribution with two degrees of freedom. The bands in the bottom panel display systematic uncertainties due to effects from the JES, the JER, and variations in the $E_T$ in simulation. Good agreement between data and simulation is observed.

events with an identified leptonically decaying $Z$ boson or an isolated photon. The measured scale and resolution in data are in agreement with the expectations from simulation. Also presented is the performance of an advanced $p_T^{\text{miss}}$ reconstruction algorithm, the “pileup per particle identification” $p_T^{\text{miss}}$, specifically developed to cope with the large pileup collisions expected at the high-luminosity LHC. This algorithm shows a significantly reduced dependence of the $p_T^{\text{miss}}$ resolution on the number of pileup collisions ($\gtrsim 10$), particularly important for the upcoming LHC data-taking periods. Finally, the performance of an algorithm ($S$) used to estimate the compatibility of the reconstructed $p_T^{\text{miss}}$ with the hypothesis that it originates from resolution effects, was studied. The $S$ shows improved performance in discriminating between events with and without genuine $p_T^{\text{miss}}$ compared to the traditional $p_T^{\text{miss}}$ reconstruction algorithms.
Figure 20. Distributions of \( S \) in data and simulation in single-muon (upper) and single-electron (lower) samples, for events with zero jet (left) and \( \geq 1 \) jet (right). The last bin includes all events with \( S > 48 \). The red straight line corresponds to a \( \chi^2 \) distribution with two degrees of freedom. The bands in the bottom panel display systematic uncertainties due to effects from the JES, the JER, and variations in the \( E_U \) in simulation. Good agreement between data and simulation is observed.

Figure 21. Dependence of the average \( S \) on pileup, for dimuon (left) and single-electron (right) events. Weak dependence is observed for processes with no genuine \( p_T^{\text{miss}} \), whereas in events with genuine \( p_T^{\text{miss}} \) the behavior of \( S \) depends strongly on primary vertex multiplicity.
Acknowledgments

We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC and thank the technical and administrative staffs at CERN and at other CMS institutes for their contributions to the success of the CMS effort. In addition, we gratefully acknowledge the computing centers and personnel of the Worldwide LHC Computing Grid for delivering so effectively the computing infrastructure essential to our analyses. Finally, we acknowledge the enduring support for the construction and operation of the LHC and the CMS detector provided by the following funding agencies: the Austrian Federal Ministry of Science, Research and Economy and the Austrian Science Fund; the Belgian Fonds de la Recherche Scientifique, and Fonds voor Wetenschappelijk Onderzoek; the Brazilian Funding Agencies (CNPq, CAPES, FAPERJ, and FAPESP); the Bulgarian Ministry of Education and Science; CERN; the Chinese Academy of Sciences, Ministry of Science and Technology, and National Natural Science Foundation of China; the Colombian Funding Agency (COLCIENCIAS); the Croatian Ministry of Science, Education and Sport, and the Croatian Science Foundation; the Research Promotion Foundation, Cyprus; the Secretariat for Higher Education, Science, Technology and Innovation, Ecuador; the Ministry of Education and Research, Estonian Research Council via IUT23-4 and IUT23-6 and European Regional Development Fund, Estonia; the Academy of Finland, Finnish Ministry of Education and Culture, and Helsinki Institute of Physics; the Institut National de Physique Nucléaire et de Physique des Particules / CNRS, and Commissariat à l’Énergie Atomique et aux Énergies Alternatives / CEA, France; the Bundesministerium für Bildung und Forschung, Deutsche Forschungsgemeinschaft, and Helmholtz-Gemeinschaft Deutscher Forschungszentren, Germany; the General Secretariat for Research and Technology, Greece; the National Research, Development and Innovation Fund, Hungary; the Department of Atomic Energy and the Department of Science and Technology, India; the Institute for Studies in Theoretical Physics and Mathematics, Iran; the Science Foundation, Ireland; the Istituto Nazionale di Fisica Nucleare, Italy; the Ministry of Science, ICT and Future Planning, and National Research Foundation (NRF), Republic of Korea; the Lithuanian Academy of Sciences; the Ministry of Education, and University of Malaya (Malaysia); the Mexican Funding Agencies (BUAP, CINVESTAV, CONACYT, LNS, SEP, and UASLP-FAI); the Ministry of Business, Innovation and Employment, New Zealand; the Pakistan Atomic Energy Commission; the Ministry of Science and Higher Education and the National Science Centre, Poland; the Fundação para a Ciência e a Tecnologia, Portugal; JINR, Dubna; the Ministry of Education and Science of the Russian Federation, the Federal Agency of Atomic Energy of the Russian Federation, Russian Academy of Sciences and the Russian Foundation for Basic Research; the Ministry of Education, Science and Technological Development of Serbia; the Secretaría de Estado de Investigación, Desarrollo e Innovación, Programa Consolider-Ingenio 2010, Plan Estatal de Investigación Científica y Técnica y de Innovación 2013-2016, Plan de Ciencia, Tecnología e Innovación 2013-2017 del Principado de Asturias and Fondo Europeo de Desarrollo Regional, Spain; the Swiss Funding Agencies (ETH Board, ETH Zurich, PSI, SNF, UniZH, Canton Zurich, and SER); the Ministry of Science and Technology, Taipei; the Thailand Center of Excellence in Physics, the Institute for the Promotion of Teaching Science and Technology of Thailand, Special Task Force for Activating Research and the National Science and Technology Development Agency of Thailand; the Scientific and Technical Research Council of Turkey, and Turkish Atomic Energy Authority; the National Academy of Sci-
